ABSTRACT

Some rare HIV-1-infected individuals, referred to as HIV controllers, have persistently undetectable plasma viral load in the absence of therapy. This control of HIV-1 replication has been associated with a strong, multifunctional specific CD8+ T cell response. However, no direct link between this immune response and the control of viremia has so far been provided.

We investigated parameters of specific CD8 T cell response and in vitro susceptibility to HIV-1 infection in 11 HIV controllers. We found high frequencies of HIV-specific CD8+ T cells. Interestingly, these cells expressed the activation marker HLA-DR but not CD38. This unique phenotype differentiates HIV-specific CD8 T cells from HIV controllers and non-controller subjects and likely reflects a high potential to expand upon exposure to antigen and a capacity to exert effector functions. Accordingly, although their CD4+ T cells were fully susceptible to HIV-1 superinfection, CD8+ T cells from HIV controllers effectively suppressed HIV-1 infection. Remarkably, this potent anti-HIV activity was observed without prior stimulation of CD8+ T cells. It was not mediated by secreted inhibitory factors, was due to the elimination of infected CD4+ T cells and was only observed with autologous CD4+ T cells, indicating an HLA-restricted cytotoxic mechanism. This constitutive antiviral capacity of CD8+ T cells could account for the control of viral replication in HIV controllers.
INTRODUCTION

Most untreated HIV-1-infected individuals have continuous viral replication and ultimately progress to AIDS. However, a rare subpopulation of HIV-infected patients spontaneously control viral replication for long periods in the absence of treatment (1-5). These individuals, referred to here as HIV controllers (HIC), are characterized by undetectable plasma HIV-1 RNA. Some HIC have been found to be infected by replication-incompetent viruses (6). However, a potent immune response to HIV-1 is thought to be pivotal in these patients (3, 7, 8).

Actually, HIC generally exhibit a strong CD8+ T cell specific response and high frequencies of HIV-specific CD8+ T cells despite very low levels of viral antigens (3, 4, 7). Furthermore, (i) HIV-specific CD8+ T cells from HIC are qualitatively different from those of progressors (8, 9); (ii) some HLA-Bw4 haplotypes (e.g. B27, B57) are over-represented in HIC (10, 11), suggesting an important role of class I-restricted CD8+ T cells; and (iii) multiepitopic and de novo CD8+ T cell responses are associated with suppression of viremia despite CTL escape mutations (12).

However, the mechanisms by which CD8+ T cells restrain HIV-1 infection in HIC are still unclear. The remarkable spontaneous viral control in HIC offers a unique model in which to shed some light on efficient in vivo mechanisms of CD8+ T cell-mediated HIV-1 control. We characterized the parameters of the CD8+ T cell response in 11 HIC from a previously described group (5), providing evidence that their HIV-specific CD8+ T cells possess a unique phenotype. In addition, we demonstrated an extraordinary capacity of their CD8+ T cells ex vivo to suppress HIV-1 infection.
RESULTS

Study Population

The characteristics of the 11 HIC are reported in Table 1. HLA alleles B57 and B27, associated with protection from progression to AIDS (10, 11), were overrepresented (7 and 4 subjects possessed these alleles, respectively).

HIV controllers exhibit large numbers of HIV-specific CD8+ T cells with variable maturation profiles

High frequencies of HIV-specific CD8+ T cells (7546 ± 5121 SFCs/10⁶ PBMCs) with a broad response (7 ± 3 peptides recognized) were observed in most HIC (Fig. 1A). Subjects bearing either the HLA-B57 or -B27 allele had the highest frequencies of HIV-specific CD8+ T cells. These frequencies were not significantly different from those of viremic controls (3719 ± 3455 SFCs/10⁶ PBMCs) but significantly higher than those of HAART subjects (758 ± 1025 SFCs/10⁶ PBMCs) (Fig. 1B).

The maturation status of HIV-specific CD8+ T cells was analyzed by measuring membrane expression of CD45 RO and the differentiation marker CD27. This combination readily identifies effector cells as being CD27- (CD27-/CD45RO+) defining classical effector cells and CD27-/CD45RO- [i.e. CD45RA+] the terminally differentiated CD8+ T cells (13)). Overall, higher percentages of CD27- (effector) HIV-specific CD8+ T cells were observed in HIC than in viremic subjects (Fig. 2A). However, the profiles were extremely heterogeneous within HIC (Fig 2A and 5) and only a minority of cells expressed high levels of perforin (2.3% ± 1.6%) whatever their maturation profile.

HIV-specific HIC CD8+ T cells possess an unusual activation profile
We examined the activation status of CD8+ T cells by evaluating HLA-DR and CD38 expression. HIV-specific CD8+ T cells showed low expression of CD38 (15% ± 9%, similar to that observed among the total CD8+ T cell population: 19% ± 5%) (Fig. 2B). In contrast, HIV-specific CD8+ T cells expressed a high level of HLA-DR (52% ± 17%), higher than that observed among total CD8+ T cells (25% ± 16%, P = 0.001) (Fig. 2B). This may suggest an activation of HIV-specific CD8+ T cells, which is unexpected in subjects with undetectable plasma RNA levels, and puzzling in the absence of high CD38 expression (Fig. 6A). Actually, HIV-specific CD8+ T cells from viremic subjects exhibited high expression of both CD38 and HLA-DR (51% ± 20% and 46 ± 21%, respectively), whereas those from HAART subjects had low expression of these two markers (11% ± 8% and 26 ± 20% for CD38 and HLA-DR, respectively), (Figure 2C and 6A). In addition to activation, expression of HLA-DR has been associated with proliferation (14). HIV-specific CD8+ T cells from HIV controllers had a high proliferation capacity (on average, 60% ± 31% of HIV-specific CD8+ T cells that proliferated) that was positively correlated to the expression of HLA-DR (P Spearman = 0.03) (data not shown). This profile may rather reflect the capacity to proliferate than ongoing proliferation in vivo, as Ki-67 expression was low on ex vivo HIV-specific CD8+ T cells (data not shown). Consistent with a high proliferative potential, in proliferation assays all CFSE\textsuperscript{low} specific CD8+ T cells were HLA-DR+ (Fig. 6B). Finally, we observed a mutually exclusive expression of HLA-DR and the CD57 marker on HIV-specific CD8+ T cells (Figure 6C and data not shown).

Ex vivo unstimulated HIC CD8+ T cells control HIV-1 infection

Seeking a direct link between the particular CD8+ T cell response in HIC and the control of viremia, we next evaluated the capacity of circulating HIC CD8+ T cells to
suppress, in the absence of exogenous stimulation, HIV-1 infection in autologous CD4+ T cells.

Purified CD4+ T cells from HIC supported viral replication at levels similar to those observed in healthy controls (2520 ± 997 and 2729 ± 1248 ng p24/ml at the peak of viral replication in the 11 HIC and 12 healthy controls, respectively) (Fig. 3A). As expected (15), the levels of viral replication in CD4+ T cells from 10 untreated viremic HIV-1-infected individuals were highly heterogeneous (2331 ± 2204 ng p24/ml) (Fig. 3A).

When cocultures of CD4+ T cells and autologous unstimulated CD8+ T cells were infected with HIV-1, viral replication was undetectable in 9 out of the 10 HIC tested (4.0 ± 1.1 log p24 decrease, CD8:CD4 vs CD4, n=10) and strongly reduced in the remaining subject, B2 (Fig. 3A) who, interestingly, showed also the lowest HIV-specific CD8+ T cell response (see Fig. 1A: 130 SFC/10⁶ PBMC, 1 peptide recognized). In contrast, unstimulated CD8+ T cells from healthy donors were devoid of antiviral activity (0.1 ± 0.2 log p24 decrease, CD8:CD4 vs CD4, n=12) and unstimulated CD8+ T cells from viremic individuals were never able to efficiently control HIV-1 superinfection in autologous CD4+ T cells (0.9 ± 0.6 log p24 decrease, CD8:CD4+ at 1:1 ratio vs CD4, n=9) (Fig. 3A). Furthermore, the antiviral activity of CD8+ T cells from viremic individuals was rapidly lost when CD8+ T cells were diluted, whereas HIC CD8+ T cells were still fully effective at a ratio of 0.1 CD8+ T cell to 1 CD4+ T cell (fig. 3B).

This remarkable anti-HIV-1 activity of unstimulated HIC CD8+ T cells was observed with a wide range of infectious doses (BaL HIV-1 m.o.i. = 10⁻².⁸ to 10⁻⁰.⁸) (data not shown) both with laboratory-adapted HIV strains and primary isolates, regardless of clade and tropism (HIV-1 NL4.3 (X4); 132W (dual tropic), subtype E; DH12 (dual...
tropic) and BX08 (R5), subtype B, (data not shown). Experiments performed without exogenous IL-2 (that was regularly present in the coculture medium) showed, as expected, a reduced viral replication in infected CD4+ T cells, but the antiviral capacity of HIC unstimulated CD8+ T cells did not depend on the presence of the cytokine (Fig. 7).

**Soluble factors are not responsible for CD8+ T cell-mediated HIV-1 control in HIV controllers**

In order to clarify the mechanism(s) responsible for the control of HIV-1 infection in the cells from HIC, we assessed the role of soluble factors (16, 17). In HIC, the control of HIV-1 replication was totally lost when unstimulated CD8+ T cells were separated from autologous CD4+ T cells by semi-permeable membranes (Fig. 4A). By contrast, when mitogen-activated CD8+ T cells were separated from autologous CD4+ T cells by semi-permeable membranes, a (modest) reduction in viral replication mediated by soluble factors, was observed in HIC and also frequently in healthy donors (Fig. 4A). Therefore HIC CD8+ T cells, although able to secrete inhibitory soluble factors upon *in vitro* stimulation, do not exert their potent anti-HIV-1 activity *ex vivo* through this mechanism.

**CD8+ T cells from HIV controllers eliminate the HIV-1 infected CD4+ T cells**

To evaluate whether the observed control of HIV-1 infection was achieved through the physical elimination of infected CD4+ T cells by HIC CD8+ T cells, we removed CD8+ T cells from superinfected autologous cocultures. The removal of the CD8+ T cells would be expected to rescue HIV-1 replication in the re-purified CD4+ T cells only if
HIV-1 control was caused by a CD8-mediated intracellular block, such as the postintegration inhibition induced by the antiviral factor CAF (18).

Single-round infections with pseudotyped HIV-1 particles were used to avoid confusing contribution of subsequent viral replication. A marked control of HIV-1 infection was observed at 48h when HIC unstimulated CD8+ T cells were cocultured with autologous CD4+ T cells (Fig. 4B, left). The coculture was then split and CD8+ T cells were depleted from one of the two resulting cocultures. Two days later a comparable strong reduction of HIV-1 infection was observed in both cultures (figure 4B, center). However, when the two cultures were re-challenged with the HIV-1 pseudotype, the CD8-depleted culture was readily superinfected whereas control of infection was still observed in the non depleted coculture (Fig. 4B, right). These results are compatible with a CD8+ T cell-mediated elimination of infected CD4+ T cells. Consistent with this, the addition of HIC CD8+ T cells to autologous CD4+ T cells that had been infected for 2 days with GFP reporter HIV-1 particles, provoked a reduction in the number of infected GFP-positive CD4+ T cells (Fig. 4C).

Anti-HIV-1 activity of HIC CD8+ T cells requires contact with autologous CD4+ T cells

The precedent results strongly supported that control of HIV-1 infection was mediated by a cytotoxic mechanism. To find out if the HIC CD8+ T cell antiviral activity was MHC-restricted, we assessed the capacity of unstimulated HIC CD8+ T cells to control HIV-1 infection in autologous and heterologous CD4+ T cells. The same HIC CD8+ T cells that were able to control HIV-1 in vitro when cocultured with autologous CD4+ T cells, were ineffective when cocultured with heterologous CD4+ T cells both from HIC
and from healthy controls (Fig. 4D). These results support an MHC-restricted mechanism of suppression.

**DISCUSSION**

Here we provide the first evidence that HIV-specific CD8+ T cells from HIV controllers are characterized by a unique \( \text{CD38}^{\text{low}}/\text{HLA-DR}^{\text{high}} \) phenotype, which likely reflects a capacity to proliferate upon antigenic stimulation and exert effector functions. Importantly, we also report that circulating HIC CD8+ T cells are able to efficiently control HIV-1 infection \textit{ex vivo}, without further stimulation, suggesting that this antiviral activity is functional \textit{in vivo}. This CD8+ T cell-mediated control is independent of the secretion of antiviral molecules, requires contact with their matching CD4+ T cells, and is caused by the elimination of infected CD4+ T cells, likely due to HIV-specific CD8+ T cells. This previously undescribed spontaneous capacity of CD8+ T cells to clear the virus through the killing of infected cells is particular to HIV controllers.

In keeping with previous studies in a comparable group of patients (7, 8), we observed that most HIC possessed high frequencies of IFN\( \gamma \)-secreting HIV-specific CD8+ T cells that, overall, did not differ from those seen in chronically viremic patients and were strikingly higher than those observed in HAART-treated non viremic patients (Fig. 1 and (7, 8, 19, 20)). These HIV-specific CD8+ T cells had a broad repertoire, particularly in HLA-B27 and/or HLA-B57-positive individuals.

The high proliferative potential observed in HIC has been previously proposed (8) together with high functionality (9) as hallmarks of a high-quality HIV-specific CD8 T+
cell response in HIC. However, no phenotypical differences had been found so far that might distinguish HIC from other patients and be associated with an effective immune response. We evaluated the differentiation status of HIC HIV-specific CD8+ T cells as the skewed maturation of these cells may partly explain the lack of effective control of HIV replication in most HIV-infected patients (21-25). We observed that HIV-specific CD8+ T cells were indeed more differentiated in HIC than in HIV-viremic patients (21, 26). Nevertheless, variable profiles were observed within and among the HIC, and, therefore, optimal differentiation of their specific CD8+ T cells does not appear as a distinctive element to explain the effective control of infection.

The activation phenotype of HIV-specific CD8+ T cells in HIC had not been previously defined. We and others have shown a positive correlation between the level of viral replication and the activation status of HIV-specific CD8+ T cells (26-28). Accordingly, and in contrast to viremic controls, CD38 expression by HIV-specific CD8+ T cells from HIV controllers was very low in this study. Conversely, HLA-DR expression was remarkably high, differently from HAART patients, and much higher than that observed on the total CD8+ T cell population. An increased HLA-DR expression associated with a low CD38 expression had been reported on the global CD8+ T cell population in asymptomatic HIV-infected patients with stable CD4+ T cell counts (29). In HIV controllers we observed that the discordance between the expression of CD38 and HLA-DR was much more pronounced on HIV-specific CD8+ T cells what is puzzling in the context of high and long-lasting viral control. The low expression of CD38 may reflect the lack of general immune activation and the expression of HLA-DR may actually characterize T cells with high proliferative potential. This hypothesis is supported by several data: (i) although we found little evidence of in vivo cycling or proliferation, as...
very few HIV-specific CD8+ T cells expressed Ki67, HIV-specific CD8+ T cells from HIV controllers had potent *in vitro* proliferative capacity upon exposure to antigen; (ii) most HLA-DR<sup>pos</sup> HIV-specific CD8+ T cells did not express the senescence marker CD57 which lack of expression has been clearly linked to proliferative capacity (30); (iii) finally, we observed a correlation between HLA-DR expression and the percentage of proliferating CFSE<sup>low</sup> cells among HIV-specific CD8+ T cells.

Although the control of HIV-1 replication in HIC has been associated with a strong, multifunctional specific CD8 T cell response, the anti-HIV activity of HIC CD8+ T cells had not been thoroughly addressed and a direct link between the immune response and the control of viremia was lacking. First, we show that HIC CD4+ T cells are highly susceptible to HIV-1 *in vitro* infection, discarding, therefore, that an intrinsic resistance of CD4+ T cells to HIV-1 could contribute to HIC status. Second, we found that HIC purified CD8+ T cells were able to efficiently control HIV-1 infection *in vitro* of autologous CD4+ T cells, even if 10 times more diluted than the CD4+ T cells. Our results are particularly relevant since our experiments were conducted with *ex vivo* CD8+ T cells, in the absence of mitogen-activation, showing that CD8+ T cells circulating in the blood of HIC are suitably prepared to control HIV-1 infection. The remarkable spontaneous anti-HIV capacity was a homogeneous feature among CD8+ T cells from HIC, except for patient B2, for whom other factors may contribute to the control of HIV infection. Differences in the CD8 T cell anti-viral activity between HIC and viremic individuals were striking since *none* of the 9 viremic controls tested suppressed the viral replication as opposed to 9 out of 10 HIC tested.
Although CD8+ T cells in HIV patients have been reported to be able to suppress HIV infection through the secretion of soluble factors (reviewed in (17)) or HLA-class I restricted cytolysis (31-33), the relative weight of these mechanisms is controversial. We demonstrate that the ability of HIC CD8+ T cells to control HIV-1 infection ex vivo is not linked to the secretion of soluble factors and required contact with infected CD4+ T cells. The contact of CD8+ T cells with CD4+ T cells did not induce the production of a restriction factor in the latter but rather the elimination of the infected cells. This antiviral activity was effective on autologous CD4+ T cells only. Altogether, our results point to HLA-restricted cytotoxicity as the mechanism associated to the in vivo control of infection achieved by HIV controllers.

In conclusion, we provide direct evidence that circulating CD8+ T cells from HIC are spontaneously able to control HIV-1 infection, a striking difference with cells from viremic subjects. Our study strongly suggests a pivotal role of HIV-specific CD8+ T cells in viral control in these individuals. These cells have a unique phenotype which may correspond to activated status in vivo but more likely reflects a propensity to expand rapidly upon antigen exposure. This capacity is probably linked to an intact ability to secrete IL-2 and other cytokines (9, 34) and may explain the maintenance of high frequencies of HIV-specific CD8+ T cells in these subjects. The generation of this optimal CD8+ T cell profile is a major research focus. Further studies should provide new insights into the precise mechanisms of HIV control and may serve to a better design of future vaccination or immune-based therapies. Already, both the expression of HLA-DR and CD38 on HIV-specific CD8+ T cells and their capacity to suppress ex vivo HIV-1 might be used as surrogate markers to evaluate the efficiency of induced CTL responses in vaccine trials.
MATERIALS AND METHODS

Study subjects

Eleven patients infected by HIV-1 for > 10 years who had never received antiretroviral treatment and in whom more than 90% of plasma HIV RNA load tests gave values <400 copies/ml (HIV controllers) were studied here: 9 have been described elsewhere (5), and 2 were newly recruited. All are infected with HIV-1 group M, clade B. HLA-typing was performed by genotype analysis (I. Theodorou, INSERM U543, Paris, France).

Among HIV-infected patients recruited and monitored at CHU Kremlin-Bicêtre, France, 42 who had an exhaustive evaluation of their HIV-specific CD8+ T cells served as controls : 24 were untreated viremic patients [HIV plasma RNA > 7,500 copies/mL] and 18 were HAART-treated, virologically controlled patients [HIV plasma RNA <200 copies/mL].

Twelve healthy controls were blood donors from the Etablissement Français du Sang, Paris, France.

All subjects gave their written informed consent.

Isolation of primary cells

CD4+ and CD8+ cells were purified (>99%) from freshly isolated peripheral blood mononuclear cells (PBMC) by positive selection with antibody-coated magnetic beads (Miltenyi Biotech, France). CD4+ cells were stimulated for 3 days with phytohaemagglutinin (PHA) at 1 μg/ml in the presence of interleukin-2 (IL-2) (Chiron, France) at 100 IU/ml. The culture medium was RPMI 1640 containing 10% FCS and penicillin/streptomycin (100 U/ml). CD8+ T cells were kept in culture without mitogens or cytokines.
Viruses and productive infection in vitro

Results shown were obtained performing infections in vitro with HIV-1 BaL (R5) at m.o.i. $10^{-2.8}$. CD4+ T cells ($10^5$) were infected in triplicate in 96-well plates with a spinoculation protocol (35). For coculture, $10^5$ CD4+ T cells were mixed with $10^5$ CD8+ T cells (CD8/CD4 ratio 1:1) or with $10^4$ CD8+ T cells (CD8/CD4 ratio 0.1:1) at the moment of infection. After infection the cells were washed and cultured for 14 days. HIV-1 replication was monitored every 3-4 days in supernatants by p24 ELISA (Beckman-Coulter, France). Unless otherwise indicated, infectivity assays were carried out in the presence of 100 IU/ml IL2.

Single-round infections

BaL and VSV-G pseudotyped HIV-1 particles were produced by co-transfecting (SuperFect, Qiagen) 293T cells with the proviral pNL-Luc-E-R+ (36) or pNL-GFP-E-R+ (37) and BaL-Env or VSV-G expression vectors. CD4+ T cells ($10^5$) were infected in triplicate with HIV-1 pseudotypes, as above. Luciferase activity was assessed in cell lysates (Luciferase Reporter 1000 Assay System, Promega France) in a Veritas microplate luminometer (Turner BioSystems, CA, USA) as described (38).

Peptides

We used a set of 124 peptides corresponding to known optimal CTL epitopes (NIH HIV Molecular Immunology Database: http://www.hiv.lanl.gov/content/immunology/index.html. The peptides were synthesized by Neosystem (Strasbourg, France). They were used at a final concentration of 2 µg/mL.
Elispot assay

Interferon (IFN)-γ secretion by HIV-specific CD8+ T cells was quantified with an ELISPOT assay using appropriate stimuli (HLA-defined optimal peptides derived from the HIV-1 Env, Gag, Pol and Nef proteins or controls) (20). IFN-γ spot-forming cells (SFCs) were counted with a KS-ELISPOT system (Carl Zeiss Vision) and expressed as SFCs/10^6 PBMC after subtracting the background. Wells were considered positive if they contained at least 50 SFCs/10^6 PBMC and exhibited at least two times the background level.

Antibodies

The following antibodies were used: CD8-ECD or -PC5 (clone B9.11), CD3-PC5 (UCHT1), CD45RO-ECD (UCHL1), HLA-DR-ECD (Immu-357), CD38-FITC (T16), and CD57-FITC (NC1) all from Beckman Coulter (San Diego, CA); and CD27-FITC (M-T271), perforin-FITC (dG9) and Ki67-FITC (B56) from BD Biosciences (San Jose, CA).

Tetramer staining and phenotyping

HIV-specific CD8+ T cells were detected with the following PE-conjugated tetramers: HLA-A*0201-SLYNTVATL (HIV gag 77-85), A*0201-ILKEPVHGV (HIV pol 476-484), A*0301-RLRPGGKKK (HIV gag 20-28), A*0301-QVPLRPMTYK (HIV nef 73-82), and B*2705-KRWIILGLNK (HIV gag 263-272) from Proimmune Ltd (Oxford, UK) and B*5701-KAFSPEVPMF (HIV gag 162-172) from Beckman Coulter Immunomics. PBMC were incubated with tetramers (1 µg/mL) for 30 min and then with relevant antibodies for 15 min. Cells were washed in Cell Wash (BD Biosciences) plus 1% BSA, incubated for 10 min with FACS lysing solution (BD Biosciences) and
washed. For intracellular staining, cells were incubated for 10 min with FACS permeabilizing solution (BD Biosciences) before adding antibodies for 30 min. Cells were fixed in 1% paraformaldehyde for flow cytometry with a Beckman Coulter Epics XL cytometer and RXP software (Beckman Coulter).

**Proliferation assay**

The proliferative capacity of HIV-specific CD8+ T cells was evaluated by flow cytometry. PBMC were stained with 0.35 µM carboxyfluorescein diacetate succinimidyl ester (CFSE, Molecular Probes, The Netherlands) for 10 min at 37°C, and then stimulated for 5 days with 2 µg/mL peptide or medium alone. After labelling with tetramer, anti-CD8, anti-CD3 and/or anti-HLA-DR antibodies, PBMC were fixed in 1% paraformaldehyde.

**Statistical analyses**

All values throughout the text are expressed as means ± standard deviation. P values were calculated with the Mann-Whitney U test. Correlations were identified by simple linear regression analysis and Spearman’s rank correlation test.

**ACKNOWLEDGEMENTS**

The authors thank Laurence Meyer from the SEROCO/HEMOCO cohort, Ioannis Theodorou and Christine Rouzioux for contributing data, and the physicians who care for the patients. We especially thank the subjects who participated in this study for their cooperation.

(A) Individual HIV-specific CD8+ CD27- T cell frequencies on CD8+ tetramer^pos^ cells (left) in 9 HIC (each symbol represents one individual, 1 to 3 specificities tested per subject) and viremic subjects. Median percentages are represented by a black line. For HIC, results obtained with B*2705-gag 263-272 and B*5701-gag 162-172 tetramers are represented in blue and orange respectively. (B) Frequencies of CD38 (blue) and HLA-DR (red) expression on total CD8+ T cells (horizontal bars) and HIV-specific CD8+ T cells (circles) in 9 HIC. (C) Comparison of CD38 and HLA-DR expression (median, 25th-75th and 10th-90th percentiles) on HIV-specific CD8+ T cells in HIC, viremic and HAART groups. Statistical differences between groups are indicated on the top of the panels.
Figure 3: Control of HIV-1 infection by ex vivo HIC CD8+ T cells

HIV-1 in vitro infection assays were done with cells from HIC, uninfected donors (control), or HIV viremic individuals [median plasma viral load was 25,350 RNA copies/ml (range 7,800-321,000)] (viremic). (A) PHA-activated CD4+ T cells were infected, in the absence (gray) or in the presence (white) of autologous unstimulated CD8+ T cells (1:1 ratio), with the replicative HIV-1 BaL. Circles represent the average (n=3 independent infections) peak p24 values for each studied individual. Horizontal lines indicate median values for each group. Statistical differences in CD8+ T cell-mediated inhibition between groups are indicated on the top of the panel. (B) PHA-activated CD4+ T cells (gray bars) and cocultures of autologous unstimulated CD8+ T cells and PHA-activated CD4+ T cells (1:1 ratio, white bars; 0.1:1 ratio, patterned bars) from 5 HIC, 5 uninfected blood donors (control), and 9 HIV viremic individuals (viremic) were infected with HIV-1 BaL. One representative experiment (HIC A9) is shown. Bars represent peak levels of p24 in supernatants (mean ± SD, n=3). Values below the dashed lines were at background level.

Figure 4: Mechanism of HIC CD8+ T cells mediated control of HIV-1 infection.

(A) CD4+ T cells from HIV controllers and from uninfected donors were infected with replicative HIV-1 BaL. CD4+ T cells cultured alone are shown as a reference (gray bars). Autologous unstimulated CD8+ T cells were added directly to the CD4+ T cell culture (blue open bars) or to Transwell inserts that were placed in the CD4+ T cell-containing well (blue patterned bars). Autologous PHA-stimulated CD8+ T cells were added to Transwell (orange patterned bars). The ratio of CD8+ to CD4+ T cells was 1:1. One representative experiment with HIV controller A1 and one uninfected control is
shown. Results are peak p24 levels. (B) CD4+ T cells from HIV controller A4 were infected with a single-round HIV-1 BaL pseudotype bearing the luciferase gene alone (gray) or in coculture (1:1 ratio) with unstimulated autologous CD8+ T cells (white). Results (mean ± SD, n=3) are the percentage of infection, relative to luciferase activity detected in lysates of infected CD4+ T cells, 48 hours after infection (left). At this time point, CD8+ T cells from half the coculture were depleted and viral replication was analysed two days later (center). Both the CD8:CD4 coculture (open bars) and the re-purified CD4+ T cells (patterned bars) were then re-challenged with the HIV-1 BaL pseudotype and luciferase activity was measured 48 hours later (right). (C) CD4+ T cells from HIV controllers were infected with a HIV-1 VSV-G pseudotype bearing the GFP reporter gene. 48 hours later autologous unstimulated CD8+ T cells were added to half of the CD4+ T cells (white, 1:1 ratio). At the indicated time points an aliquot of each cell suspension was labelled with anti-CD4 antibodies and the quantity of double positive CD4+GFP+ was assessed by flow cytometry. One representative experiment with HIC A7 is shown. (D) Unstimulated CD8+ T cells from HIC (A1, A3 and B5) (circles) and uninfected blood donors (squares) were cocultured (1:1 ratio) with autologous or heterologous HIC CD4+ T cells (A1:A3, A3:A1 and B5:A7, CD8:CD4 T cell cultures) or uninfected controls CD4+ T cells and infected with replicative HIV-1 BaL. Results (average of 3 independent infections) are peak p24 levels.
