The inflammasome pathway is activated in response to a variety of pathogens and plays an important role in shaping adaptive immunity. Yet, the spatiotemporal orchestration of inflammasome activation *in vivo* and the mechanisms by which it promotes an effective immune response remain to be fully understood. Using an *in vivo* reporter to visualize inflammasome assembly, we establish the distribution, kinetics and propagation of the inflammasome response to a local viral infection. We show that Modified Vaccinia Ankara virus induces inflammasome activation in subcapsular sinus (SCS) macrophages, immediately followed by cell death and release of extracellular ASC specks. This transient inflammasome signaling in the lymph node generates a robust influx of inflammatory cells, and importantly, mobilizes T cells from the circulation to increase the magnitude of T cell responses. We propose that, in response to infection, SCS macrophages deliver a burst response of inflammasome activity and cell death that translates into the broadening of T cell responses, identifying an important advantage of inflammasome driven vaccination strategies.

Introduction

Innate immune sensing of pathogens or damage is characterized by activation of membrane and cytosolic pattern recognition receptors (PRR) including Toll-like receptors (TLRs), retinoic acid inducible gene I-like helicase receptors (RLRs), cytosolic DNA sensors, and nucleotide oligomerization domain-like receptors (NLRs)¹. The inflammasome forms part of this first line response, mediated primarily by phagocytic antigen-presenting cells such as macrophages and dendritic cells, and refers to a hetero-multimeric protein scaffold which is assembled upon activation of cytosolic PRRs². Multiple inflammasome complexes exist, each being triggered by several cytosolic sensor protein families with specificities for distinct pattern-recognition motifs². Once activated, many of these sensors associate with a common adaptor protein known as ASC (apoptosis-like speck protein with a CARD domain, *Pycard*), which promotes recruitment and proximity-induced autocatalytic maturation of caspase-1³. These processes occur through prion-like polymerization of ASC into filaments and ultimately result in the formation of micrometer-sized structures referred to as ASC specks⁴.

Inflammatory effector mechanisms unleashed by active caspase-1 include the proteolytic processing and release of bioactive interleukins 1 β and 18 (IL-1 β , IL-18), and induction of cellular pyroptotic death^{4,5}. *In vitro*, ASC speck formation can coincide with cell death and cytokine release^{6,7} but the relationship between inflammasome activation *in vivo* and induction of cell death remains to be documented. Recent studies have provided evidence that ASC specks can exist as active extracellular structures, raising interest in the fate and dynamics of ASC specks after cell death^{8,9}. Despite our increasing knowledge of effector mechanisms induced by the inflammasome response, we still have a limited understanding of how inflammasome activation unfolds *in vivo*. In particular, the location and timing of inflammasome activity in tissue remain unclear, as do the immediate effects of cellular inflammasome activity. While several fluorescent probes have been developed to study

inflammasome activation *in vitro*¹⁰⁻¹², their use for *in vivo* applications has remained challenging, lacking translation to single cell resolution at the organ level^{10,12,13}.

Another aspect of inflammasome biology is to understand how its activity regulates innate and adaptive immunity. Pro-inflammatory IL-1 and IL-18 have been shown to play roles in both local and peripheral recruitment and priming of the immune response¹⁴⁻¹⁶, and absence of inflammasome activity has been associated with poorer pathogen clearance and increased disease severity¹⁷⁻²¹. Mechanisms that link the inflammasome pathway to T cell responses include danger associated molecular pattern (DAMP)-mediated dendritic cell (DC) activation²², effects of inflammatory cytokines on T cell polarization²³ and activation, or non-cognate induction of IFN- γ in memory T cells^{16,24}. In this respect, understanding the spatiotemporal dynamics of inflammasome activation may help clarify the downstream effects on the T cell response. Here, we establish an *in vivo* reporter system to visualize inflammasome activation in real-time and dissect its influence on the immune response following a local viral infection.

Results

MVA induces inflammasome activation in macrophages

To examine local viral infection as an inflammasome trigger, we selected Modified Vaccinia Ankara virus (MVA), a replication deficient group I dsDNA poxvirus used in clinical vaccination programmes, with strong immunogenicity through activation of endosomal TLRs and cytosolic MDA-5, AIM2 and NLRP3²⁵⁻²⁷. As such, it delivers a temporally defined stimulus for inflammasome activation, allowing a model for direct monitoring of downstream cellular events of infection. Using both wild type (WT) and Caspase-1 (*Casp1*^{-/-}/*Casp4/11*^{-/-}) deficient mouse strains, we confirmed that MVA infection induced inflammasome activity in bone-marrow derived macrophages (BMDM), by detection of caspase-1 activity (**Fig. 1a and Supplementary Fig. 1a**) and IL-1 β **Fig. 1b**. Addition of Z-YVAD-FMK caspase-1 specific inhibitor prevented IL-1 β release induced by adenosine triphosphate (ATP) treatment of LPS-primed BMDM and by MVA-infected BMDM, demonstrating that IL-1 β release depended on the conventional inflammasome pathway^{28,29}.

To detect inflammasome activation in real-time, we stably transduced BMDM to express a fusion protein of ASC and green fluorescent protein (ASC-GFP), as a read-out for inflammasome assembly. As anticipated, MVA infection induced formation of ASC ‘speck’ inflammasomes *in vitro* (**Fig. 1c–d**), which could be visualised by redistribution of ASC-GFP protein as it oligomerizes to form a single macromolecular complex³⁰ (**Supplementary movie 1**). Concomitant with inflammasome activity, MVA infection also induced caspase-1 dependent macrophage death (**Fig. 1e**). *In vitro* ASC-overexpression did not alter cellular levels of caspase-1 activity, IL-1 β release, nor the kinetics or amount of cell death (**Supplementary Fig. 1b–f**), which corresponds with a recent report highlighting the critical role of the levels of upstream inflammasome sensor proteins in determining the rate of speck

formation⁴. *In vivo* after local viral infection (subcutaneous (s.c.) footpad injection) with MVA, we found that virus primarily targeted macrophages within the subcapsular (SCS-M) and medullary (Med-M) regions of the draining lymph node, consistent with previous reports of their role in sequestering lymph borne pathogens³¹⁻³³ (**Supplementary Fig. 2**). MVA infection resulted in rapid and specific loss of lymph node macrophages, most notably CD169⁺ F4/80⁻ SCS-M (**Fig. 1f–g**). These findings suggest that inflammasome signaling and pyroptotic death may be an important component of the immune response to MVA.

SCS macrophages initiate the inflammasome response to MVA

Detection of inflammasome activity *in vivo* at single cell resolution has so far been restricted to static imaging on fixed tissue sections³⁴, limiting our understanding of the identity, dynamics and fate of cells undergoing inflammasome activation. This is in part due to the lack of mouse models to detect inflammasome activation and in part due to the inherently transient nature of cell signaling which may ultimately progress to cellular demise.

To circumvent this limitation, we developed a strategy for dynamic two-photon imaging of inflammasome assembly by *in vivo* detection of ASC speck formation. Mixed bone marrow chimeric mice were generated by transfer of cycling bone marrow-derived haematopoietic stem cells (BM-HSC), retrovirally transduced to express ASC-GFP fusion protein. ASC-GFP-expressing BM-HSC, derived from *Rag2*^{-/-} mice, were mixed with either WT or caspase-1-deficient BM-HSC, and used to reconstitute recipient mice (**Fig. 2a**). This strategy served to restrict reporter expression to the myeloid compartment, and limit caspase-1-dependent functional inflammasome signaling to those cells expressing the reporter. Within lymph nodes of chimeric mice, ASC-GFP was expressed by myeloid cells, with a normal distribution throughout the lymph node volume (**Supplementary Fig. 3a–b**). Intravital imaging of chimeric mice revealed, in particular, ASC-GFP expression by cells localized to

the subcapsular sinus region of resting lymph nodes (**Fig. 2b**). These cells formed a dense network at the lymph node periphery, displayed a macrophage-like morphology and were stained following *in vivo* injection of a CD169-specific antibody (**Fig. 2c**), indicating myeloid-derived reconstitution of lymph node subcapsular sinus macrophages, as previously described³⁵.

When ASC-GFP chimeric mice were injected s.c. with MVA, we detected ASC speck formation occurring primarily within these macrophages in draining lymph nodes (**Fig. 2d and Supplementary movie 2**). Of note, we did not observe ASC speck formation in control mice injected with PBS (**Fig. 2e and Supplementary movie 3**). Single-cell analysis of the redistribution of ASC-GFP protein leading to speck assembly, revealed a rapid and dynamic cellular process (**Fig. 2f–g**), with the majority of cells undergoing complete ASC oligomerization within 10 minutes (mode 2.8; median 6; range 2–99 mins) (**Fig. 3a and Supplementary Fig. 3c**).

We next quantified ASC speck formation occurring during the first 12 hours following local MVA injection and identified an acute inflammasome response, detectable within one hour following infection and peaking over the subsequent 2 hours (**Fig. 3c**). For these analyses, we counted ASC specks forming during the imaging (forming ASC specks) as well as ASC specks already formed (formed ASC specks) at the time of imaging. Inflammasome activation then steadily declined until neither active speck formation, nor formed specks were detected at 12 hours. The number of ASC specks detected following infection corresponded with the kinetics of SCS-M loss observed by histological and lymph node cell suspension analysis methods shown earlier (**Fig. 1f–g**). Thus the steady decline in the numbers of specks detected post-infection, likely reflects the loss of SCS-macrophages. Throughout the imaging period, ASC specks were not detected in lymph nodes of PBS-injected controls, nor within deeper regions of the lymph node accessible by two-photon imaging following MVA

injection (**Supplementary movie 4**). Further analysis of the relative spatial arrangement of specks in the lymph node revealed that the majority were localised to within 30 μm of the subcapsular region, indicated by the presence of capsular collagen fibers (**Fig. 3c** and **Supplementary Fig. 3d–e**). When compiled, these data reveal a rapid triggering of ASC speck formation, generating a transient and spatially confined wave of inflammasome activity spanning the first 7 hours following infection.

Cell death and release of extracellular ASC specks *in vivo*

Pyroptosis is a caspase-1 dependent form of cell death³⁶, which unlike other modes of cell death, is an inflammatory event associated with cell swelling, membrane lysis and nuclear condensation³⁷. Using time-lapse microscopy of BMDM we examined infection (MVA-GFP), inflammasome activation (ASC-mcherry) and cell death (DNA binding SytoxBlue) events in parallel (**Fig. 4a** and **Supplementary movie 5**). Dynamic analysis of virally encoded GFP and nuclear stain intensities revealed that ASC speck formation in BMDM was closely followed by loss of cell integrity and cellular demise (**Fig. 4b**). This rapid process of cell death occurred within minutes following inflammasome assembly (mode 3 min; median 7 min; range 0–40 min) and was largely intrinsic to cell infection, with no appreciable cell-to-cell transactivation of the inflammasome response to infection (**Supplementary Fig. 4a–b**). We next examined the process of ASC speck formation and cell death by *in vivo* labelling of lymph nodes with the cell permeable nuclear DNA binding dye Hoechst 33342, enabling detection of cell death events by tracking nuclear condensation. Intravital imaging revealed that macrophages undergoing inflammasome activation died rapidly after speck formation, progressing firstly to nuclear condensation and then disappearance of the nucleus (**Fig. 4c**, **Supplementary Fig. 4c**).

While examining *in vivo* Hoechst labelling of draining lymph nodes, we noted that the vast majority of formed specks we detected did not have any associated nuclei, suggesting they were remnants of cells after inflammasome activation. To more firmly establish this hypothesis, we injected a fluorescently conjugated ASC-specific antibody into MVA-treated ASC-GFP chimeric mice. Formed specks were counterstained with the ASC antibody, confirming their extracellular nature (**Fig. 4d**). Intravital tracking of formed specks over several hours revealed that many specks are long-lived entities, persisting over 4 hours within the lymph node microenvironment (**Fig. 4e**). Moreover, we observed that specks generated *in vivo* either remained as long-lasting structures, gradually diminished in size and eventually disappeared, suddenly disappeared, or fragmented into multiple specks (**Fig. 4e,f** and **Supplementary movie 6**). In addition, on several occasions we also observed the acquisition of specks by other cells within the lymph node (**Supplementary movie 7**). These *in vivo* observations are consistent with two recent reports describing the ability of macrophages to phagocytize formed specks *in vitro*, with the potential to precipitate inflammasome activation within the engulfing cell ^{8,9}.

In vivo analysis of inflammasome activity also revealed a phenomenon whereby ASC speck formation and subsequent cell death resulted in a rapid localized recruitment and clustering of resident cells towards newly generated specks (**Fig. 4g** and **Supplementary movie 8**). Such recruitment occurred within minutes following speck formation and cell death, and could be detected using either Hoechst staining or by tracking myeloid cells (GFP⁺) in ASC-GFP chimeras (**Supplementary movie 8**). In summary, our results describe the rapid and localized initiation of inflammasome activation in the lymph node on viral infection results in macrophage death, persistence of extracellular ASC specks and local cell recruitment.

Inflammasome signaling generates a robust influx of inflammatory cells

Our *in vivo* analysis revealed that inflammasome activation induced by MVA is restricted in both time and space within the lymph node. Therefore, we next assessed how inflammasome signaling translated to activation of the innate and adaptive immune response by performing whole lymph node screening of chemokine mediators expressed early (4 hours) after local viral infection (**Fig. 5a**). We identified a rapid production of chemokines induced by MVA, many of which were reduced in the absence of caspase-1 or IL-1 receptor signaling (CCL11, CCL22, CXCL2, CXCL10, CCL19). This shows that a transient wave of inflammasome activation elicited by MVA is a potent modulator of the chemokine release in draining lymph nodes. Consistent with these data and previous reports on chemokine release induced by MVA^{25,38}, this was associated with rapid and robust infiltration of neutrophils, monocytes and NK cells to the lymph node. Innate immune cell recruitment was substantially reduced in the absence of caspase-1 or IL-1R1 signaling (**Fig. 5b-d, supplementary Fig. 5**).

To identify which cellular compartment was responsible for responding to inflammasome-derived IL-1 signals, BM chimeric mice were generated in which only hematopoietic cells (WT BM > *Il1r1*^{-/-}), or only non-hematopoietically derived cells (*Il1r1*^{-/-} BM > WT) expressed IL-1R1. Infection-induced recruitment of neutrophils and monocytes was abolished in the absence of haematopoietic cellular sensing of IL-1, and was partially diminished by non-hematopoietic cell expression of IL-1R (**Fig. 5e,f**). This indicates that cells of predominantly hematopoietic origin relay IL-1 signals in the lymph node to promote infiltration of innate cells to the draining lymph node.

Inflammasome signals broaden the composition of T cell responses

To assess the contribution of inflammasome activation towards the adaptive immune response, we focused on the generation of the antigen-specific CD8⁺ T cell response directed

against the immunodominant vaccinia viral peptide (VVp) B8R 20-27 expressed by MVA (**Fig. 6a**). Lack of caspase-1 activity or IL-1R1 expression resulted in moderately lower percentages of antigen-specific T cells induced by MVA infection (**Fig. 6b**). However, both caspase-1 and IL-1R1 deficient mice had reduced absolute numbers of VVp-specific cells (**Fig. 6c**).

We hypothesized that an overall increase in leukocyte infiltration induced by inflammasome activity may potentially lead to more naïve T cells being recruited to the draining lymph node for priming and activation. Indeed, functional inflammasome and IL-1R signaling promoted the overall accumulation of CD8⁺ T cells in the draining lymph node as early as 18 hours following MVA injection (**Fig. 6d,e**). To test whether inflammasome activation favors the recruitment of T cells, which were not initially present in the lymph node, T cells were transferred into WT, caspase-1- or IL-1R1-deficient recipients, followed immediately by local MVA infection (**Fig. 6f**) so that the majority of transferred T cells were present in the circulation at the time of infection. A combination of T cells were transferred that could be subsequently re-traced *in vivo*, each at a different ratio to provide minor circulating T cell populations, in order to simulate an *in vivo* limiting dilution assay. The specific contribution of transferred T cells in the bulk of the VVp specific T cell pool at the peak of the response was analysed in order to evaluate the mobilization of T cells that were not initially present in the lymph node. In WT mice, a large fraction of the VVp response was derived from the transferred T cell populations. However, this contribution was largely reduced in caspase-1 deficient and even more so in IL-1R deficient mice (**Fig. 6g,h**). In particular, the CFP⁺ T cells (that were transferred in the lowest numbers) were virtually absent from the VVp-specific response in caspase-1 and IL-1R deficient mice. We confirmed that this effect was attributed to the defective early recruitment of adoptively transferred T cells from the circulation to infection draining lymph nodes, in the absence of inflammasome

signaling (**Supplementary Fig. 6**). As expected, delaying MVA injection until 48 hours after T cell transfer, allowing time for transferred T cells to equilibrate within lymphoid organs, resulted in the overall T cell response being less dependent upon early inflammasome-driven T cell recruitment, with transferred T cells making similar contributions towards the overall VVp specific T cell response in WT mice and mice with disrupted inflammasome signaling (**Supplementary Fig. 6b**).

In line with these findings, blocking T cell trafficking to the draining lymph node during MVA infection in WT mice, using a CD62L-specific blocking antibody, resulted in a significant reduction in the number of VVp specific T cells (**Supplementary Fig. 7a,b**). Furthermore, analysis of IFN- γ T cell responses to other H-2K^b restricted peptide epitopes for MVA (A3L, K3L, A19L, A8R), showed that blocking T cell recruitment also reduced the diversity of the T cell response (**Supplementary Fig. 7c,d**) further highlighting the importance of T cell trafficking to the draining lymph node for optimal responses. These data indicate that inflammasome activation increases the magnitude and broadens the potential repertoire of the T cell response by mobilizing antigen-specific T cell clones from the periphery.

Discussion

Secondary lymphoid organs are key locations for initiation of innate host defence and priming of the adaptive response. Here we provide evidence of a host immune circuit linking activation of these two arms of the response to deliver effective immunity, which is coordinated through inflammasome signaling initiated by subcapsular macrophage sensing of infection.

Methods to detect inflammasome activation *in situ* have so far been very limited, relying primarily on tissue histological staining for speck protein components, active caspase-1 or mature IL-1 β ^{8,39-41}. This task is further complicated by the close link between inflammasome activation and cell death, and the inherent difficulty in detecting such transient events⁴². Our approach circumvents these limitations by probing the inflammasome in real-time and in single cells using intravital imaging. A potential caveat of our strategy may be that ASC overexpression alters the timing of inflammasome activation. However, this was not observed *in vitro*, and furthermore, the kinetics of the immune response to MVA and SCS macrophage death in our chimeras was similar to that observed in wild-type mice, suggesting that overexpression of the probe has no obvious effects on the observed response. With the ability to detect the cell type, location and timing of inflammasome pathway, we provide the first glimpse into the dynamics of inflammasome activation in the context of lymph borne virus. As recent *in vitro* studies have demonstrated that the kinetics of caspase-1 activation are essentially the same irrespective of the intensity or types of stimulus^{4,43}, our results may be directly relevant to other types of pathogenic challenges *in vivo*.

A recent study by Kastenmuller et al. has indicated a strong role for the inflammasome pathway in innate immune cell activation and recruitment in response to lymph borne pathogens, highlighting an important role of SCS macrophages in the context of IL-18 and IL-

1 β release¹⁶. In addition, this report and our previous work have shown that SCS depletion alter neutrophils and NK cell recruitment in the draining lymph node upon viral challenge, respectively^{16,33}. The present results extend these findings by directly demonstrating that macrophages in the subcapsular area of the lymph node rapidly undergo inflammasome activation, which is immediately followed by pyroptotic cell death. Although our data support the idea that SCS macrophages are the major population undergoing inflammasome activation during the early phase of the response, it is likely that other cell types, such as inflammatory monocytes or neutrophils, may also contribute towards the inflammasome response during later stages of infection^{44,45}. Our results provide *in vivo* support for the idea that the inflammasome acts as a digital switch, whereby pyroptosis coincides with a burst-release of pro-inflammatory cytokines, which are rapidly processed by concomitant caspase-1 activation, a phenomenon recently described *in vitro*^{42,43}. Thus, *in vivo*, inflammasome signaling by subcapsular sinus macrophages likely delivers a concentrated and localized inflammatory stimulus to surrounding cells, defining a discrete anatomical compartmentalization of the inflammasome response.

Extracellular ASC specks are active when injected *in vivo*^{8,9}, but their generation *in situ* has not previously been characterized. We now directly demonstrate that most ASC specks persist for several hours as extracellular structures before showing signs of degradation. Detection of speck fragmentation and engulfment *in vivo*, suggests these events may provide potential mechanisms of amplifying the inflammasome response, and warrant further examination of the functional relevance of these phenomena in contributing towards the immune response.

One potential consequence of lymph borne infection is the alteration of the SCS macrophage layer. Neutrophil or dendritic cell infiltration can contribute to disrupt and/or destroy this layer^{46,47}. Our results establish pyroptosis as an additional, direct mechanism

accounting for the clearance of CD169⁺ SCS macrophages observed during infection⁴⁷. Local recruitment of myeloid cells triggered by inflammasome activation and pyroptosis is reminiscent of neutrophil clustering previously observed around dying cells^{46,48,49}. While this immediate response is likely due to the release of local mediators upon cell death such as extracellular ATP or other DAMPs⁵⁰⁻⁵², our results suggest that subsequent IL-1 sensing by hematopoietic cells largely amplifies the initial inflammasome signals. This second level of signal propagation resulting in chemokine production and cellular recruitment to the draining lymph node may therefore work in concert with other mechanisms of lymph node remodelling induced by infection, such as vascular and lymph angiogenesis leading to increased organ volume⁵³.

Emerging data is highlighting the importance of inflammasome regulation of the adaptive T cell response, in the context of vaccine adjuvanticity, infection and autoimmune disorders⁵⁴⁻⁵⁶. In several studies, lack of inflammasome activity has been shown to result in a poorer T cell response to infection^{19,57,58}. Triggering of the inflammasome pathway may increase the quality of antigen-presentation or act on T cell differentiation and expansion through the direct action of IL-1^{24,59,60}. Here, we have uncovered an additional mechanism whereby inflammasome activation enhances the magnitude and breadth of composition of T cell responses by promoting recruitment of T cells from the periphery. Vaccine vectors such as MVA that engage the inflammasome pathway may therefore be advantageous to mobilize a maximal number of antigen-specific T cell clones in the draining lymph node.

In summary, our results reveal an immune circuit operating in lymph nodes in which a spatially compartmentalized wave of inflammasome activation translates into the massive recruitment of innate and adaptive immune cells that ultimately maximises T cell responses. Our novel approach to probe inflammasome activity *in vivo* will allow dissecting the contribution of this pathway during vaccination, infections or inflammatory diseases.

Figure legends

Figure 1. MVA infection induces inflammasome activation, speck formation and rapid loss of SCS macrophages in draining lymph nodes. (a) Detection of caspase-1 activity (FLICA-1⁺ staining) in wild-type (WT) and Caspase-1 deficient (*Casp1*^{-/-}) bone marrow derived macrophages (BMDM), 6 h after infection with MVA (multiplicity of infection, MOI). (b) IL-1 β release in WT BMDM cultured with MVA or LPS and ATP (black bars), is inhibited by addition (white bars) of caspase-1 inhibitor z-YVAD-FMK. (c) Three consecutive images (2 min intervals) from time-lapse microscopy of BMDM (cell outlined by dashed line) expressing ASC-GFP (green), showing ASC-GFP protein redistribution leading to speck formation induced 6 h after infection with MVA (MOI = 25) (Scale bar: 10 μ m), representative example from more than 10 independent experiments. (d) Detection of ASC specks in cultures of WT BMDM expressing ASC-GFP, 15 h after treatment with MVA or LPS + ATP. (e) Percentage of dying cells (propidium iodide stain⁺) in WT or *Casp1*^{-/-} BMDM cultures detected 6 h after MVA infection by flow cytometry. (f) Immunofluorescent staining of CD169⁺ antigen in popliteal lymph nodes from WT mice up to 18 h after s.c. injection of 5 \times 10⁶ pfu MVA, showing loss of SCS-macrophages (SCS-M) from subcapsular sinus regions of lymph nodes (Scale bar: 100 μ m, representative of four experiments, *n* = 3 mice per group). (g) Flow cytometry detection of numbers of lymph node SCS-M, Medullary macrophage (Med-M), macrophage and dendritic cell (DC) subsets in WT mice after injection of MVA (Representative of more than six experiments, *n* = 6 mice per time point). Data (a, b, e) are representative of more than three experiments performed in triplicates. All charts plot mean \pm s.e.m. ***P* < 0.01, ****P* < 0.001 compared to WT or vehicle using (d) one-way analysis of variance (ANOVA) followed by Tukey's post hoc test for multiple comparison or (e,g) Student's *t*-test.

Figure 2. Dynamic imaging of inflammasome activation in ASC-GFP retrogenic mice reveals rapid kinetics of cellular inflammasome signaling. (a) Schematic of chimeras generated by transfer of *Rag2*^{-/-} bone marrow derived haematopoietic stem cells (BM-HSC), transduced to express ASC-GFP protein, into irradiated recipient mice, in combination with WT or *Casp1*^{-/-} BM cells. (b) Intravital microscopy images of popliteal lymph node in ASC-GFP BM-chimeras, showing GFP (green) expression in cells localised to the lymph node collagen capsule (white, second harmonics generation, SHG). Dashed line indicates lymph node edge (Scale bar: 30 μ m). (c) Intravital view of ASC-GFP BM-chimeric mouse lymph node following *in vivo* staining with a CD169-specific antibody, showing GFP⁺ cell and CD169 colocalization in the subcapsular sinus region (Scale bar: 30 μ m). Intravital images of ASC-GFP BM-chimeric mouse lymph node over a time (*t*) interval of 1 h, showing multiple ASC speck formation events (arrows) occurring following injection with (d) MVA but not (e) PBS injection. Dashed lines indicate lymph node edge and delineate individual ASC-GFP expressing cells (Scale bar: 30 μ m). (f) Intravital images of ASC speck formation in a lymph node macrophage 3 h after local infection with MVA (*t* = relative to start of ASC-GFP redistribution during speck formation, scale bar: 10 μ m). (g) Kinetics of speck formation *in vivo* detected by redistribution of ASC-GFP protein (change in mean GFP intensity) from cell cytoplasm (clear circles) to the speck region (green circles) within a single lymph node macrophage on local MVA infection. Data shown (b–f) are representative of 36 individual mice and (g) representative of more than 40 independent events.

Figure 3. Subcapsular macrophages provide a spatiotemporally defined inflammasome response to local viral infection. (a) Intravital tracking of ASC speck formation and its kinetics in popliteal lymph node following local MVA infection. Each horizontal line

represents an individual ASC-GFP⁺ cell and each square represents a 10 min time period. **(b)** Quantification of inflammasome activity in draining lymph node 0–12 h following local injection of PBS (triangles) or MVA (circles). Axes show the number of formed (left axis, green circles) and actively forming (right axis, red circles) ASC specks detected by intravital microscopy, acquired over more than 125 movies where each dot represents the mean \pm s.e.m number of events detected at each experimental time point ($n = 8$ –33 movies acquired from at least three mice analyzed over each time point shown). Data fit to a Log Gaussian curve is presented. **(c)** Plot showing the percentage of ASC-GFP specks detected at distances up to 100 μ m relative to the position of the lymph node capsule (0 μ m; identified by second harmonics signal generation by collagen fibers). Data shows mean \pm s.e.m percentage of 35 speck events detected within 11 imaging fields (five independent experiments) each acquired with up to 100 μ m imaging depths. Data shown (a, c) are compiled of more than 40 independent events.

Figure 4. ASC aggregation precedes rapid cell death releasing long-lived extracellular ASC specks *in vivo*. **(a)** Time-lapse microscopy (hh:mm post infection) of WT BMDM expressing ASC-mCherry protein (top panel), showing nuclear staining with SytoxBlue occurs rapidly following speck formation, on infection with MVA-GFP (merged, middle panel). Transmitted light images confirm cell death (lower panel) (Scale bar: 10 μ m). Representative images from more than five independent experiments. **(b)** Following infection with MVA-GFP, changes in BMDM cytoplasmic GFP intensity (left axis) and nuclear SytoxBlue (right axis), show rapid loss of cell integrity relative to time (min) of full ASC speck formation (red line). Plot shows mean fluorescence intensity values (\pm s.e.m) of 25 cellular events as shown in (a). **(c)** *In situ* staining of lymph node macrophages with Hoechst 33342 in ASC-GFP BM-chimeric mice shows MVA-induced ASC formation is associated

with rapid nuclear condensation (Scale bar: 10 μm). Dotted lines outline detectable cell cytoplasm and nuclear regions. **(d)** Intravital imaging of ASC-GFP BM-chimeric mouse lymph nodes following MVA treatment (6 h) show locally injected ASC-specific PE antibody colocalize with formed ASC-GFP specks (Scale bar: 40 μm , inset images 20 μm). **(e)** Intravital tracking of formed ASC specks induced by MVA infection show they are long lasting entities with variable fates. Horizontal lines in summary table represent an individual formed speck tracked *in vivo*, where each square describes changes in specks observed over 10-minute periods. **(f)** Representative intravital images of speck fates (Scale bar: 10 μm). **(g)** *In situ* staining of lymph node resident cells with Hoechst 33342, followed by intravital imaging reveals ASC speck formation (green) induces rapid local cell recruitment and clustering in lymph nodes of ASC-GFP BM-chimeric mice during MVA infection (scale bar: 10 μm). Examples shown are representative of three (d) or five (c,g) independent experiments, (e,f) are representative of more than 80 independent events ($n = 28$ mice).

Figure 5. Inflammasome activation regulates the magnitude of the inflammatory innate infiltrate into draining lymph nodes. **(a)** Whole lymph node tissue chemokine profiling performed 4 h after MVA or PBS injection in WT, *Casp1*^{-/-} and *Il1r1*^{-/-} mice, where values shown are detected protein levels normalised to total lymph node protein content ($n = 3$). **(b–d)** Absolute numbers of CD11b^{hi}Ly6G⁺ neutrophils, Ly6C^{hi}CD11b⁺ monocytes and NK cells detected in lymph nodes by flow cytometry, up to 18 h after s.c. MVA infection in WT (black filled circles), *Casp1*^{-/-} (clear circles) and *Il1r1*^{-/-} (grey filled circles) mice. Plots show combined data from more than six independent experiments. **(e,f)** Absolute numbers of neutrophils (e) and monocytes (f) detected in lymph nodes of BM chimeric mice (*Il1r1*^{-/-} > WT, red bars; WT > *Il1r1*^{-/-}, grey bars; control group WT > WT, black bars) by flow cytometry, 4 h (left plot) and 18 h (right plot) after MVA infection or in PBS controls. Data

shown ($n = 5$ animals per group) is representative of two independent experiments. All charts plot mean \pm s.e.m. $**P < 0.01$, $***P < 0.001$ compared to WT or vehicle using one-way analysis of variance (ANOVA) with Tukey's multiple comparison test (b-f) or Mann-Whitney U test (a) $*P < 0.001$.

Figure 6. Inflammasome signals recruit circulating antigen-specific T cells to the draining lymph node. (a) Flow cytometry pentamer (H2K^b-TSY) staining for detection of MVA vaccinia B8R peptide-specific T cells in draining lymph nodes 6 days post-infection, summarized as (b) percentages (of total CD8⁺ T cells) and (c) absolute cell numbers in WT, *Casp1*^{-/-} and *Il1r1*^{-/-} mice. Representative plots and experiments are shown ($n = 5$ mice). (d) Absolute numbers of CD3⁺ and (e) CD8⁺ T cells detected in lymph nodes by flow cytometry, up to 18 h after s.c. MVA infection. (f) Schematic representation of the experimental approach, involving transfer of cyan fluorescent protein (CFP) or CD45.1⁺ T cells into CD45.2⁺ recipient mice (1:2 ratio), followed by draining lymph node (dLN) analysis. Combined data from three independent experiments ($n = 8$ mice). (g,h) Representative plots of the composition of H2K^b-TSY-specific CD8⁺ T in draining lymph nodes, 6 days after MVA infection, showing transferred CFP⁺ (blue) and CD45.1⁺ (red) T cells, where percentages as a proportion of total pentamer-specific T cells are represented in the pie charts. All charts plot mean and error bars represent the s.e.m. $**P < 0.01$, $***P < 0.001$ compared to WT, using one-way ANOVA with Tukey's multiple comparison test.

Online methods

Mice. Wild type (WT) C57Bl/6 mice were purchased from Charles River France. Caspase-1 deficient (*Casp1*^{-/-}/*Casp4*/*11*^{-/-}, B6N.129S2-Casp1^{tm1Flv}/J)⁶¹, IL-1R1 deficient (*Il1r1*^{-/-}, B6.129S7-Il1r1^{tm1Imx}/J), C57Bl/6 *rag2*^{-/-}, CD45.1⁺ (B6.SJL-Ptprc^aPepc^b/BoyJ), C57Bl/6-GFP (GFP expressed under the ubiquitin promoter) and C57Bl/6-CFP (CFP expressed under the actin promoter) mice were bred in our animal facility under specific pathogen-free conditions and littermates were randomly assigned to experimental treatment groups. Experimental protocols were ethically approved by the Institutional Committees on Animal Welfare at Institut Pasteur and conducted in strict accordance with French guidelines for animal care and use.

Treatments & Reagents

Recombinant MVA-B (expressing full-length HIV Gag, fused to 3 Pol and 2 Nef fragments)⁶² was provided by the Agence Nationale de Recherche sur le Sida (ANRS), and a recombinant MVA-B strain expressing enhanced GFP was provided by Transgene Laboratories (Strasbourg, France). Mice were injected subcutaneously (s.c.) in the footpad with 5×10⁶ pfu of MVA. *In vivo* labeling of CD169⁺ cells was performed by s.c. injection of 0.5μg PE-conjugated anti-CD169 antibody (Biolegend, clone 3D6.112) approximately 1 hour before imaging. *In vivo* staining of extracellular ASC specks was performed by injection of 0.5μg AF555-conjugated anti-ASC antibody (Bioss Antibodies, bs-6741R-A555) 6 hours after MVA or PBS injection, and imaging commenced within 30 minutes. Whole lymph node labeling with Hoechst 33342 (33342 trihydrochloride, trihydrate, Invitrogen) was performed by s.c. injection of 10μL of a 0.1μM solution prepared in PBS and imaging commenced within 30 minutes. The investigators were not blinded during experiments or data analysis. *In vivo* blockade of CD62L, was performed by i.v. injection of 100μg blocking antibody

(ebioscience, MEL-14) 6 hours before MVA injection and a further 24 hours after MVA injection. WT mice were treated with a neutralizing IL-1 β antibody (R&D systems, AF-401-NA), by administration of 100 μ g i.p. 1 hour before T cell transfer or MVA injection.

Flow cytometry

To detect caspase activity, macrophages (0.2×10^6 cells) were seeded in ultra-low attachment 24-well plates (Corning) overnight and then stimulated with MVA expressing a fluorescent protein to monitor infection, at 1, 5, 25 or 50 multiplicity of infection (MOI) for 6-10 hours. Cells were gently harvested and stained with a FLICA-1 FITC (caspase-1 probe FAM-YVAD-FMK) and FLICA-3/7 660 (caspases-3/7 FAM-DEVD-FMK) kits according to the manufacturers' instructions (Immunochemistry Technologies). Control cultures were treated with 1 μ M Staurosporine (STS) (Sigma) to induce caspase-3 activity. To detect tissue infection by MVA and inflammatory cell recruitment, popliteal lymph nodes were teased apart using forceps and digested in RPMI 1640 medium containing 1 mg/ml collagenase D and 50 ng/ml DNase (Sigma) for 15 minutes at 37°C, and then passed through a 70- μ m cell strainer. Virally expressed GFP was detectable directly by flow cytometry. Cell-surface staining was performed using the following antibodies at a dilution of 1:200 (0.5 μ g/mL) unless specified, in the presence of blocking anti-CD16/32 (eBioscience, clone 93) and following exclusion of doublets and dead cells (Live/dead fixable dyes, Invitrogen): anti-CD3 (17A2), anti-NK.1.1 (PK136), anti-CD8 (53-6.7), anti-CD19 (1D3), anti-CD169 (3D6.112/MOMA-1, AbD Serotec), anti-CD11b (M1/70, BD), anti-F4/80 (BM8), anti-CD45.1 (A20), anti-CD45.2 (104), anti-CD11c (N418), (1:500) anti-I-A/E (M5/114.15.2), (1:400) anti-Ly-6G (1A8), anti-Ly-6C (AL-21), all from Biolegend or other suppliers where indicated. Cell subset analysis was performed based on the following phenotypic gating definitions: CD3⁻ CD11b⁺ CD169⁺ F4/80⁻ for SCS-M, CD3⁻ CD11b⁺ CD169⁺ F4/80⁺ for Med-M, CD3⁻ Ly6G⁻ CD169⁻

CD11b⁺ for macrophages, CD3⁻ I-A/E^{hi} CD11c⁺ for DCs, CD3⁻ Ly6G⁻ Ly6C^{hi} CD11b⁺ for inflammatory monocytes, CD11b^{hi} Ly6G⁺ for neutrophils and CD11b⁺ NK1.1⁺ for NKs cells. Absolute cell numbers were quantified using AccuCheck bead microspheres (Life Technologies) during flow acquisition. Intracellular staining was performed using the Cytofix/Cytoperm kit (BD Bioscience) using APC-conjugated anti-GranzymeB (GB11, BD biosciences) and FITC-conjugated anti-IFN γ (XMG1.2, ebioscience). Analyses were performed using an LSRII Cytometer (BD Biosciences) and analyzed using FlowJo software version 10.6 (Tree Star). Cell death induced by MVA was detected in BMDM cultures infected with MVA-GFP by counterstaining with 2.5 μ g/mL propidium iodide (Sigma).

ELISA

For ELISA detection of IL-1 β in cell free supernatants, BMDM were cultured overnight with MVA (multiplicity of infection (MOI): 1-50) or 1 μ g/mL LPS (serotype 026:B6, Sigma) in the presence or absence of 75 μ M caspase-1 inhibitor Z-YVAD-FMK (R&D Systems). The next day LPS treated cells were pulsed with 5mM adenosine 5'-triphosphate disodium salt hydrate ATP for 1 hour. Supernatants were harvested and analyzed using IL-1 β DuoSet ELISA kit according to the manufacturer's instructions (R&D Systems).

Inflammasome ASC probe generation

Constructs ASC-GFP (enhanced GFP) or ASC-mCherry (monomeric cherry)⁶³ encoding the full sequence of ASC, with fluorescent protein tagged onto the 5' sequence end, were cloned into a murine stem cell viral (MSCV) vector using standard techniques. Retrovirus was generated by co-transfection of ASC-MSCV (30 μ g) and pCI-Eco (10 μ g) plasmid DNA into HEK 293T cells using Lipofectamine 2000 transfection reagent (60 μ L) (Life Technologies), in Opti-MEM media (Gibco), which was quenched after 8 hours with Dulbecco's Modified

Eagle Medium (DMEM) containing 10% FBS, 1% Penicillin/ streptomycin. After overnight incubation at 37°C, culture media was replaced with either complete DMEM or Iscove's Modified Dulbecco's Medium (IMDM), if the retrovirus was to be used for transduction of BMDM or hematopoietic stem cells (HSCs), respectively. Retrovirus containing supernatant was harvested from 293T cell cultures during the next 2 days, filtered (0.45µM) and used to perform sequential rounds of BMDM and HSC transduction as described below.

Bone marrow derived macrophage generation and transduction

Murine bone marrow derived macrophages (BMDM) from WT or *Casp1*^{-/-} mice were differentiated from bone marrow (1-1.5×10⁶ cells seeded in 9.5cm² wells) by culture in DMEM, 10% FBS, 1% Penicillin/ Streptomycin, 1% Hepes (4-(2-hydroxyethyl)-1-piperazineethanesulfonic acid) (all from Gibco) with 20ng/mL (macrophage-colony stimulating factor) M-CSF (eBioscience) or 20% L929 supernatant, and used at day 7. BMDM were stably transduced to express ASC-GFP/ mCherry by adding retroviral-conditioned medium to macrophage cultures on days 3 and 4 during their differentiation. Retroviral supernatant was supplemented with fresh DMEM, 10% FBS, 14µg/mL Polybrene (Sigma), 1% Hepes and 20ng/mL M-CSF (eBioscience) was used to replace media on BMDM cultures and incubated at 37°C overnight. This was repeated the following day, where after overnight culture, retroviral media was replaced with fresh culture media. Transduction efficiencies of >70% were routinely achieved.

Time-lapse videomicroscopy

Macrophages transduced to express ASC-GFP or ASC-mCherry (0.2×10⁶ cells) were seeded in 35mm FluoroDish cell culture dishes (World Precision Instruments) in phenol-red free RPMI supplemented with 10% FBS, 1% Penicillin/ Streptomycin and 10ng/mL M-CSF for 6

hours, with additional 1 µg/mL LPS where indicated. Immediately prior to imaging, cell media was replaced with media containing MVA, MVA-GFP or 5mM ATP and supplemented with 0.1 µM SytoxBlue (Invitrogen). Time-lapse microscopy was performed using a DMI6000B inverted microscope (Leica Microsystems) equipped with heated chamber for temperature, humidity, and CO₂ control, with a 10X/ 0.75 NA dry objective (Olympus) and a CoolSNAP HQ2 Roper camera (Photometrics) for 15 hours after induction. Videos were analyzed using ImageJ or FiJi softwares (National Institutes of Health, <http://rsb.info.nih.gov/ij/>).

Bone marrow chimeras

To generate mixed BM chimeric mice for intravital imaging of inflammasome activity, lethally irradiated mice were reconstituted with BM-derived HSCs, retrovirally transduced to stably express ASC-GFP protein. Donor HSCs used for reconstitution were negatively selected (Miltenyi, Lineage depletion kit) from C57Bl/6 *Rag*^{-/-} BM (to achieve myeloid-restricted probe expression) and cultured overnight ($2-3 \times 10^6$ cells/ 9.5cm² well) in complete Iscove's Modified Dulbecco's Medium (IMDM), supplemented with 10% FBS, 1% Hepes, 0.1% 2-mercaptoethanol, 20ng/mL Stem cell factor/ c-Kit ligand (SCF) and 10 ng/mL Thrombopoietin (TPO). After culture overnight, HSC cell cultures were resuspended in ASC-GFP retroviral supernatant (supplemented with 10% FBS, 1% Hepes, 0.1% 2-mercaptoethanol, 20ng/mL SCF, 10ng/mL TPO, 10 µg/mL Polybrene) and spun-transduced at 1000g, 32°C for 90 minutes. Fresh complete IMDM media was added after a further 4-6 hours incubation at 37°C. This was repeated the following day, with the exception that 4-6 hours after spin-transduction, HSCs were harvested, washed in fresh media, and seeded onto pre-prepared 10cm² dishes of OP-9 feeder cells (ATCC)⁶⁴ in complete IMDM media. Cultures were harvested after a further 36-48 hours and ASC-GFP⁺ cells sorted on a FACSaria II (Becton Dickinson). Recipient WT mice were lethally irradiated by x-ray (8.5

grays, X-Xstrahl RS320), 4-6 hours before injection of $>0.2 \times 10^6$ ASC-GFP HSCs per mouse. Sorted ASC-GFP⁺ HSCs were injected in combination with either WT or *Casp1*^{-/-} BM HSCs to achieve 90%-10% chimerism. This served to restrict caspase-1 functional inflammasome signaling only to probe expressing cells when used for experiments to examine inflammasome effector functions, and also enabled a discrete distribution of ASC-GFP⁺ cells for easier single cell tracking *in vivo*. Chimeric mice had a normal lymphoid architecture as mixed chimeras were generated partially with replete BM to reconstitute the lymphoid compartment. Recipient mice were administered with sulfamethoxazole and trimethoprim supplemented water (Roche) for the following 2 weeks, and were used after >8 weeks following BM reconstitution, which was verified by histological and flow cytometry examination of blood and lymphoid tissues. Bone marrow chimeric mice to study IL-1 sensing were prepared by transferring freshly isolated bone marrow cells ($50-100 \times 10^6$ cells) derived from CD45.1⁺ *Il1r1*^{-/-} mice into lethally irradiated CD45.2⁺ WT recipients. Reconstitution of typically $>95\%$ was confirmed by blood and lymphoid tissue congenic marker expression.

Whole tissue chemokine profiling

Multianalyte profiling of whole popliteal lymph node tissue homogenates was made by RodentMAP analysis (MyriadRBM). Popliteal lymph node specimens were prepared 4 hours after MVA or PBS injection by pooling 4 excised lymph nodes and homogenising tissues using a Potter-Elvehjem homogenizer in 350 μ l of lysis buffer (50 mM Tris-HCL pH 7.4, 2 mM EDTA) containing aprotinin, antipain, leupeptin, and pepstatin A (all at 1 μ g/mL) and 2mM PMSF (phenylmethylsulfonyl fluoride), at 4°C (Roche Diagnostics). Total protein content of each tissue lysate was quantified (BCA Assay, Pierce, Rockford USA) and used to normalize concentrations of analytes detected within each sample, to the total sample protein content.

Immunofluorescence histological analysis

Whole excised lymph nodes were fixed at 4°C overnight in paraformaldehyde and progressively dehydrated in sucrose. Tissues were snap frozen in OCT compound (Tissue-Tek; Sakura) and 8µm thick tissue cryosections prepared. Antibody staining of F4/80, CD169 and GFP (Invitrogen, PA1-46326) was performed following blocking in mouse and rat serum, and sections imaged using a confocal microscope (Olympus BX61WI).

Intravital two-photon imaging

Two-photon imaging of intact popliteal lymph node was performed as previously described^{65, 66}, using an upright microscope (DM6000B, Leica Microsystems) with a 20X/0.95 NA water-dipping objective (Olympus). Excitation was provided by a Chameleon Ultra Ti:Sapphire (Coherent) tuned to 950nm. The following filter sets were used for imaging second harmonics generation (SHG)/ GFP/ PE, and Hoechst/ GFP: 483/32 BP, 495 LP, 520/35 BP, 562 LP, 607/20 B; 483/32 BP, 495 LP, 520/35 BP. Image fields of 1024×1024 pixels, with a mean pixel size of 0.5µm, z-spacing of 4µm and a volume depth of up to 100µm were recorded. Datasets were processed and analyzed using Imaris (Bitplane) and FiJi softwares.

Antigen-specific T cell detection

Antigen-specific T cell responses induced by MVA were detected within spleen and draining popliteal lymph nodes 6 days after infection, using contralateral PBS treated lymph nodes as controls. CD8⁺ T cells with specificity for the immunodominant vaccinia viral peptide (VVp) B8R 20-27 were detected by pentamer staining (PE-conjugated H2-K^b-TSYKFESV, Proimmune) of whole lymphoid cell suspensions, in CD8⁺ CD19⁻ and NK1.1⁻ gated cells by flow cytometry. For adoptive transfer assays to assess recruitment and antigen-specific T cell

priming of peripherally recruited T cells, we purified CD3⁺ T cells from C57Bl/6-GFP (20×10⁶ cells), or C57Bl/6-CFP and CD45.1⁺ mice (10×10⁶ and 20×10⁶ cells respectively) and injected cells 10×10⁶ and 20×10⁶ cells respectively into CD45.2⁺ WT, *Casp1*^{-/-} and *Il1r1*^{-/-} mice, followed by s.c. injection of MVA. Six days later, draining lymph node cell suspensions were analyzed by flow cytometry to detect the proportion of transferred cells within pentamer⁺ CD8⁺ CD19⁻ and NK1.1⁻ populations. To examine the H2-K^b restricted antigen-specific CD8⁺ T cell response to MVA peptide antigens A8R (189, ITYRFYLI), A3L (270-277, KSYNYMLL), B8R (20-27, TSYKFESV), K3L (6-15, YSLPNAGDVI), and A19L (47-55, VSLDYINTM) (Polypeptide Laboratories), 1×10⁶ cells isolated from draining lymph nodes 6 days after MVA injection, were cultured in the presence or absence of 1µg/mL of each peptide and 1x GolgiPlug (BD bioscience) in complete medium for 4 hours, followed by intra-cellular cytokine staining.

Statistical analyses

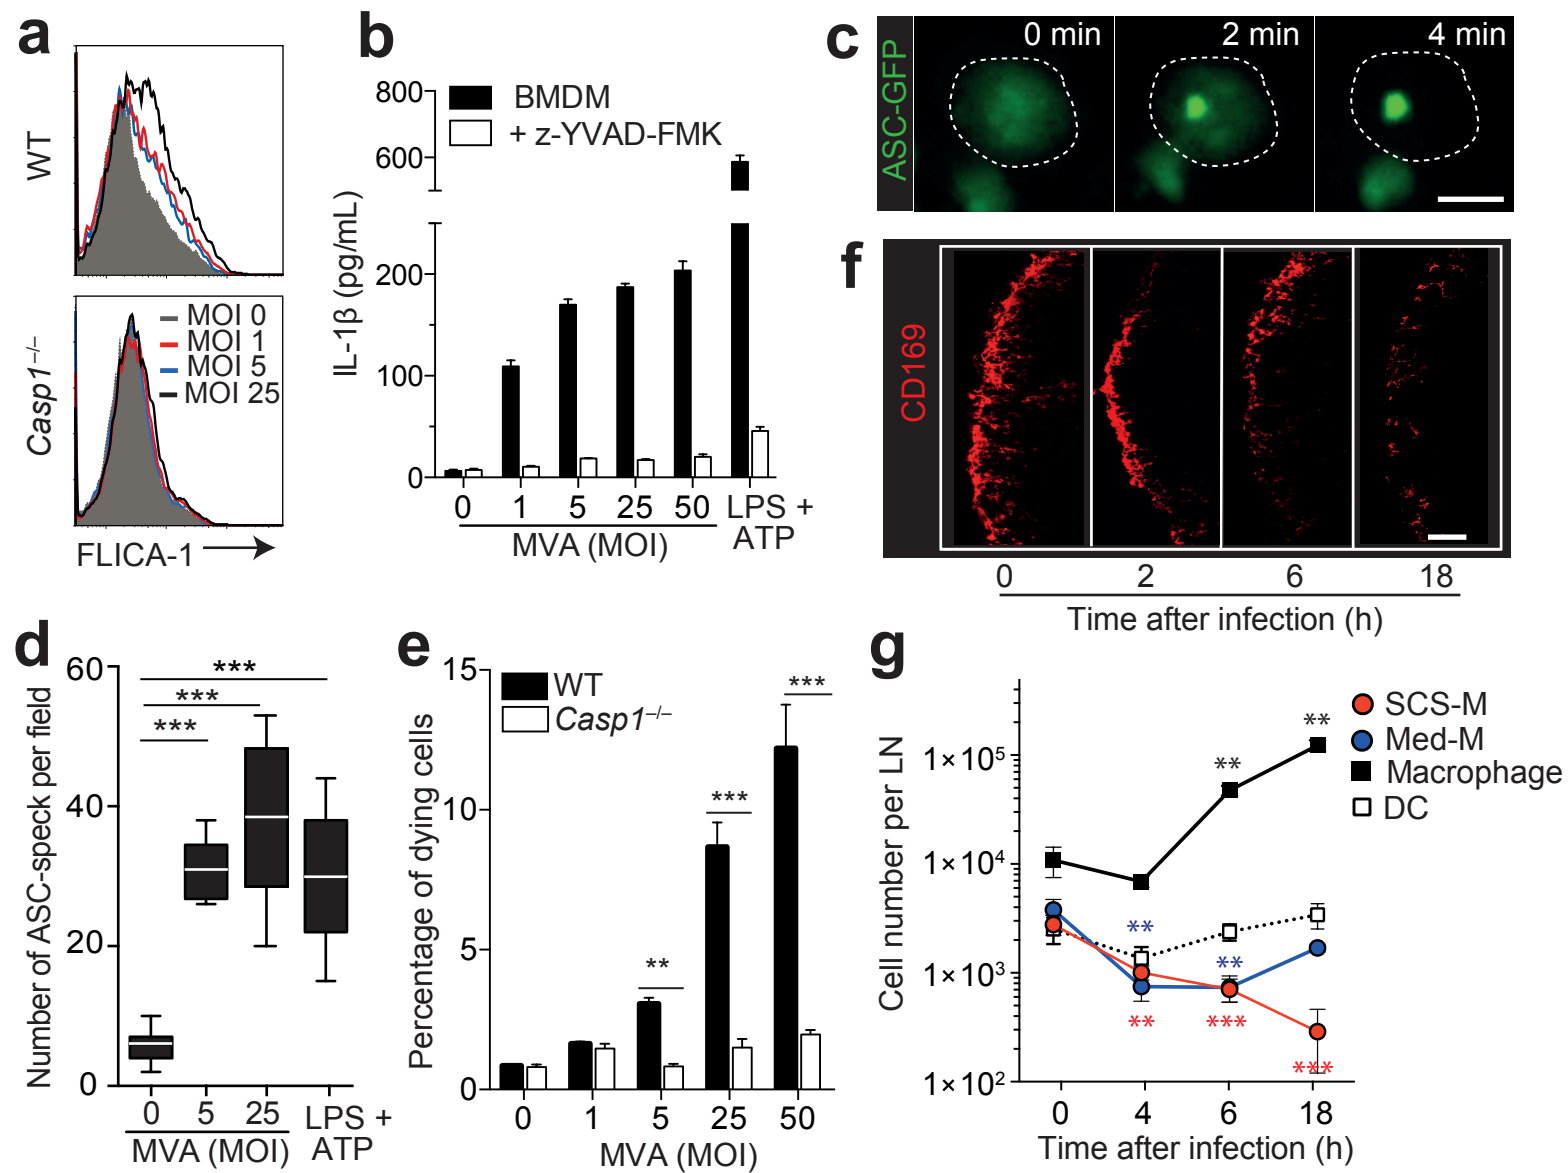

All statistical tests were performed using Prism v6.0b (GraphPad) and all data are represented as mean ± SEM. Group comparisons were assessed with non-parametric tests. We used Student's *t* test for two groups comparison or Kruskal-Wallis test for multiple comparisons. One-way ANOVA test followed by Tukey's post hoc test was used for multiple comparisons of data with normal distribution and equal variance. All statistical tests were two-tailed with a significance level of 0.05. **P* < 0.05, ***P* < 0.01, ****P* < 0.001, ns non-significant. No statistical test was used to predetermine sample size and all samples were included in the analysis.
