HAL is a multi-disciplinary open access archive for the deposit and dissemination of scientific research documents, whether they are published or not. The documents may come from teaching and research institutions in France or abroad, or from public or private research centers.

L’archive ouverte pluridisciplinaire HAL, est destinée au dépôt et à la diffusion de documents scientifiques de niveau recherche, publiés ou non, émanant des établissements d’enseignement et de recherche français ou étrangers, des laboratoires publics ou privés.
The authors provide us with a clear message that to improve patients' QoL at the EOL we need to decrease the aggressiveness of care and provide better support to our patients. Hence, urgent change in our practice for patients coming close to the EOL is required. Oncologists need to decrease likely ineffective and toxic chemotherapy, given that this may have a negative impact on both QoL and survival. However difficult, we need to have honest EOL discussions with our patients, which can facilitate this transition from disease-directed therapy to care focusing on palliation of symptoms and improving QoL. Previous work from the CWC study has shown that EOL discussions reduce aggressive care and thus improve QoL, result in EOL care more consistent with patients' preferences, and reduce health care costs in the final week of life. Furthermore, improving patients' symptoms and QoL can be achieved by further training of oncologists in palliative care, by involving other members of the multidisciplinary team (eg, psychologists, chaplains) and by referring patients with advanced, incurable cancer to palliative care.

In reply

We agree with Dr Charalambous that the message of our findings is that to improve the quality of life for patients with advanced cancer at the end of life, there needs to be a reduction in the intensity of medical care (eg, the number of intensive care unit stays, use of ventilators) they receive, as well as heightened attention to their psychosocial and spiritual needs. Dr Charalambous has taken these results as evidence to support his recommendation that oncologists be trained in palliative care and psychologists, chaplains, and palliative care clinicians be involved in multidisciplinary care of the patient. This suggestion appears to be consistent with our findings, but there is an additional related “take-home” point.

Many oncologists express frustration and a sense of futility in caring for their incurable patients. Oncologists have shared that they sometimes feel that they have little to offer such patients. This may prompt a need to respond by offering overly aggressive medical care. Many oncologists have voiced a preference for others whom they consider better trained in these areas to attend to advanced cancer patients' psychosocial needs. Patients and family members, however, express fears and disappointment regarding what they perceive to be oncologist emotional detachment and abandonment. What the results of our report indicate is that building a therapeutic alliance with patients with advanced cancer (eg, a sense of trust, empathic concern, shared goals) may be the best and most potent medicine oncologists have to offer their dying patients. Oncologists who are able to be emotionally available and attentive to patients' psychosocial and spiritual needs have the power to improve the quality of life of their patients with advanced cancer who are confronting death.
due to the long duration of cART before treatment interruption. To our knowledge, only 4 cohort studies have described patients fulfilling the criteria for PTC, and all included patients who started treatment during PHI. It is particularly noteworthy that the frequency of PTCs in these cohort studies increased linearly with the median duration of cART prior to treatment interruption, from 4.2% in the CASCADE (Concerted Action on Seroconversion to AIDS and Death in Europe) study1 (median duration of cART, 1.3 years) to 7.9% in the ANRS (Agence Nationale de Recherche sur le Sida) CO6 PRIMO cohort3 (median, 1.4 years), 8.3% in a Dutch cohort4 (median, 1.7 years), and 15.6% in our study2 (median, 2.4 years). In the SPARTAC (Short Pulse Anti Retroviral Therapy at HIV Seroconversion) study,5 in which the median duration of cART was 0.25 years, there were no PTCs. Note that no more than 0.5% of patients spontaneously control HIV replication after PHI.

We believe the main reason why PTC status is a rare phenomenon is the small number of patients who are prescribed long-term treatment at the time of PHI and then undergo scheduled treatment interruption (only 1% of patients in the CASCADE study).

At all events, evidence supporting the existence of PTC status continues to accumulate. This phenomenon has important implications in the search for a functional cure for HIV infection and further supports early treatment, especially given the potency and good tolerability of current drugs.

Hocqueloux et al propose that longer duration of combined antiretroviral therapy (cART) in primary human immuno-deficiency virus (HIV) infection (PHI) is associated with a higher probability of creating posttreatment controllers (PTCs). They cite as evidence the superior proportion of PTCs in their study compared with ours (15.6% vs 5.5%), as well as a number of studies that would support their hypothesis.1-5 While longer duration of cART administered during PHI may lead to a higher proportion of individuals controlling viral replication on its withdrawal, a hypothesis not supported by their own study or the ANRS (Agence Nationale de Recherche sur le Sida) CO6 PRIMO study by Gouyard et al,3 studies differ by a number of factors other than treatment duration. Therefore, inference about the effect of cART duration from raw figures derived from published studies is inappropriate. In any case, it is erroneous to state that there were no PTCs in the SPARTAC (Short Pulse Anti Retroviral Therapy at HIV Seroconversion) study, which could not be deduced from the citation provided.5

In the study by Hocqueloux et al,1 the time at risk following treatment discontinuation was conditioned on not resuming cART within 24 months of discontinuation. In our study no such condition was required, since all individuals who had interrupted cART (and were suppressed at the time) contributed to the risk set until they experienced an event (viral rebound) or their follow-up was censored. The comparative figure from our study would be 8.5% (11 of 130 who did not reinitiate cART within 24 months of discontinuation).

Finally, the denominator (25 629) used to derive the 1% from CASCADE (Concerted Action on Seroconversion to AIDS and Death in Europe) who were treated at the time of PHI and subsequently stopped treatment is inaccurate and results in underestimating that proportion for our study. The appropriate denominator is of individuals with an HIV test interval less than 3 months, with at least 3 months of follow-up, at least 1 HIV RNA measurement, and who seroconverted from 1996 onwards and would have, therefore, had the opportunity to have been treated with cART. Of 4010 such individuals in CASCADE, 259 (6.5%) interrupted cART.

In conclusion, while the original study by Hocqueloux et al highlighted the existence of PTC, the key question is whether early treatment during PHI can help establish post-treatment control.

High-Five for High-Sensitivity Cardiac Troponin T: Depends on the Precision and Analytical Platform

Reichel and colleagues have developed an algorithm for ruling-in or ruling-out myocardial infarction (MI) within 1 hour after presentation using high-sensitivity cardiac troponin T (hs-cTnT) for patients within the Advantageous Predictors of Acute Coronary Syndrome Evaluation study. The data analyses using classification and regression tree analysis for ruling-in via a training and validation set are powerful for supporting a 1-hour sampling/testing algorithm, albeit there is a major limitation in that both groups are from the same study population. Most strikingly, however, is the analytical criteria that was developed in this study to rule-in an MI, specifically, that either a hs-cTnT concentration of 52 ng/L or greater (to convert to micrograms per liter, multiply by 0.001) or a change (delta) in hs-cTnT concentrations of 5 ng/L or greater within 1 hour was used to rule-in. The absolute concentration of 52 ng/L is not the published 99th percentile for this assay and is in fact similar to the fourth generation’s troponin T 10% coefficient of variation (CV) concentration of 0.03 ng/L, which has been shown in a large prospective study to predict death within 30 days. More intriguing is the 5-ng/L absolute change in hs-cTnT concentrations. On the basis of reported precision data, the 10% intragroup coefficient of variation is 13 ng/L; using established laborato­ry medicine practices, acceptable variation would permit concentrations ranging from 15.6 ng/L to 10.4 ng/L around this point estimate. Thus, the imprecision of the assay alone could result in a change of 5 ng/L or greater in absence of any clinical change.

To avoid this assay imprecision trap, one may wish to (1) incorporate a longer time between samples to rule-in (ie, 3 hours; as was recently suggested for high-sensitivity assays) or (2) use a more precise platform to measure hs-cTnT. For the first point, the longer the time between blood sampling, the more likely the troponin concentration will increase with the difference (delta) exceeding the analytical imprecision. For the second point, there are analytical platforms that have different precision profiles. The E-modular platform is more precise than the Elecsys 2010 platform, with the latter often yielding imprecision that would result in 5 ng/L or greater change in concentrations. Finally, prospective studies assessing this algo­rithm should compare this shorter interval (ie, 1 hour) to a longer time interval (ie, 3 hours) for measurements and should also report on the platform and precision data for the hs-cTnT testing during the study. These are important points that should be addressed before considering adopting this algorithm for clinical care.
