Abstract The immune response is a first-line systemic defense to curb tumorigenesis and metastasis. Much effort has been invested to design antitumor interventions that would boost the immune system in its fight to defeat or contain cancerous growth. Tumor vaccination protocols, transfer of tumor-associated-antigen-specific T cells, T cell activity-regulating antibodies, and recombinant cytokines are counted among a toolbox filled with immunotherapeutic options. Although the mechanistic underpinnings of tumor immune control remain to be deciphered, these are studied with the goal of cancer cell destruction. In contrast, tumor dormancy is considered as a dangerous equilibrium between cell proliferation and cell death. There is, however, emerging evidence that tumor immune control can be achieved in the absence of overt cancer cell death. Here, we propose cytokine-induced senescence (CIS) by transfer of T helper-1 cells (T_H1) or by recombinant cytokines as a novel therapeutic intervention for cancer treatment. Immunity-induced senescence triggers a stable cell cycle arrest of cancer cells. It engages the immune system to construct defensive, isolating barriers around tumors, and prevents tumor growth through the delivery or induction of T_H1-cytokines in the tumor microenvironment. Keeping cancer cells in a non-proliferating state is a strategy, which directly copes with the lost homeostasis of aggressive tumors. As most studies

show that even after efficient cancer therapies minimal residual disease persists, we suggest that therapies should include immune-mediated senescence for cancer surveillance. CIS has the goal to control the residual tumor and to transform a deadly disease into a state of silent tumor persistence.

1 Cellular senescence

1.1 The concept of cellular senescence

Cellular senescence has been linked to a number of physiological and patho-physiological conditions such as aging, age-related diseases, tissue homeostasis, and embryogenesis (for review see [1]). In the context of aging of multicellular organisms, cellular senescence has been described as one of the nine hallmarks of aging. Besides, senescence is considered to be part of the compensatory or antagonistic damage responses [2]. Some senescence-associated biomarkers, foremost the cell cycle inhibitor cyclin-dependent kinase inhibitor 2A (p16^{Ink4a}) and telomere-damage induced foci (TIFS), accumulate in cells of various tissues of aged individuals, indicating that senescence and aging are closely linked [3, 4]. Importantly, elimination of senescent cells from aged tissues improves overall tissue fitness [5], whereas the tissue-degenerative effects of senescence are likely to be transmitted by the senescence-associated secretory phenotype (SASP), at least in part [6] (Fig. 1a). Developmental senescence (Fig. 1b) is a physiologically programmed senescence pathway that has recently been described to actively contribute to embryonic patterning [7, 8]. This process is also accompanied by a SASP that attracts macrophages which in turn seem to be necessary to remove senescent cells in a coordinate manner in order to foster the physical

Fig. 1 Cellular senescence in aging, embryogenesis, and tumorigenesis. **a** During aging of the organism, normal cells may enter the cell cycle. After several cell divisions, the chromosomal telomere length decreases and the expression of the cell cycle inhibitor $p16^{\text{Ink4a}}$ increases. This leads to permanent arrest of the cell cycle and in the case of “old” cells to replicative senescence. Senescent cells produce secretory factors, and the SASP may contribute to enhanced tissue degeneration in older individuals. **b** During embryogenesis, some embryonic cells may run through the cell cycle leading to $p53$ -independent $p21$ accumulation and permanent cell cycle arrest. On the one hand, these “old” embryonic cells produce secretory factors (SASP), and on the other hand, the senescent cells are cleared by macrophages. Both mechanisms then contribute to the tissue shaping during embryogenesis. **c** During

tumorigenesis, normal cells may enter an accelerated cell cycle (for example by activation of oncogenes). These rapidly cycling tumor cells upregulate $p53$ and the cell cycle inhibitor $p16^{\text{Ink4a}}$ leading to permanent cell cycle arrest or oncogene-induced senescence. The tumor cells can also be driven into senescence by other cellular stressors, e.g., by drugs or cytokines. Interestingly, tumor cell senescence can both exert a pro- or antitumoral effect. Whereas the components of the SASP have been shown to enhance tumor growth, the macrophage-mediated clearance of senescent tumor cells inhibits tumor growth. $M\Phi$ macrophages, $p16^{\text{Ink4a}}$ cyclin-dependent kinase inhibitor 2A, $p21$ cyclin-dependent kinase inhibitor 1, $p53$ cellular tumor antigen $p53$, SASP senescence-associated secretory phenotype

development of the embryo (Fig. 1b). In contrast, oncogene- or therapy-induced premature senescence is a mere stress response mechanism (Fig. 1c). It is a cell intrinsic anticancer mechanism that is triggered by various genetic or epigenetic perturbations including hyperactive oncogenes [9, 10], cytotoxic drugs [11, 12], or by cytokines [13–15] leading to an essentially irreversible cell cycle arrest. Oncogene-induced senescence is eventually accompanied by macrophage-mediated removal of the affected cancer cells, and this clearance mechanism of senescent cancers substantially improves the anti-cancer defense machinery of the immune system [16]. On the other hand, it is still unclear whether the

SASP, which is an integral part of oncogene- as well as cytokine-induced senescence, and leads to the secretion of various chemokines and growth factors, may play a tumor-promoting role, and should therefore be considered as harmful [17]. Thus, it is currently believed that it is necessary to clear senescent cells from the organism.

1.2 Cytokine-induced senescence

Cytotoxic cancer therapy is currently the gold standard of clinical practice. A bevy of cytotoxic regimens has been

developed over six decades to destroy or remove cancerous tissue. The complete surgical excision of cancer tissue including all adjacent or distant metastases is the most effective curative treatment option. It may be accompanied or followed by other mainly cytotoxic therapies, i.e., radiation therapy [18], chemotherapy [19], or cytotoxic immunotherapy [20, 21]. These therapies rely on (i) the induction of programmed cell death [19, 22]; (ii) caspase-independent programmed necrotic cell death [23, 24] or necroptosis, that is dependent on the ripoptosome [25]; (iii) autophagic cell death [26]; (iv) target cell lysis [21]; and (v) respiratory burst mediated by neutrophils [27].

The common goal of all cytotoxic therapies is the ultimate destruction of the cancer cells [28]. In clear contrast, pro-senescence therapy is not aimed at destroying cancer cells but to contain their expansion and thus can be considered as a non-destructive alternative tumor control mechanism [14, 15, 29–31]. In principle, cancer cell senescence can be triggered by intrinsic or extrinsic pathways (Fig. 2). The intrinsic pathways are triggered by reactivation/stabilization of the tumor suppressor protein p53 [32], by inactivation of the oncogene Myc [33], or by tumor suppressor phosphatase and tensin homolog deleted on chromosome 10 (Pten) inhibition by VO-OHpic [34]. Pten inhibition-induced senescence (PICS) in prostate cancer is especially intriguing, as loss of Pten is usually associated with oncogenesis, e.g., in aggressive breast cancer [35] or in follicular thyroid carcinomas [36]. Thus, the fate of a given precancerous cell after Pten loss may strongly depend on its ancestry and/or its molecular background. Nevertheless, the three intrinsic senescence pathways mentioned above lead to cell cycle arrest (Fig. 2a). The activation of these pathways results either in tumor growth inhibition or in tumor regression. Therapy-induced cancer cell senescence can be induced by genotoxic stress, i.e., by drugs targeting genomic DNA (Fig. 2b). Thus, doxorubicin [37] or cyclophosphamide treatment [12] induces a senescence-like phenotype in tumor cells. However, chemotherapeutics rather induce a mixed response including both apoptosis and senescence. In most cases, the senescent phenotype is only observed when the apoptosis machinery has been inhibited [12]. Thus, targeted therapies, like the B-Raf inhibitor vemurafenib, trigger senescence primarily in apoptosis-resistant melanoma cells [38]. First hints that not only membrane-penetrating drugs with a low molecular weight can induce intrinsic senescence pathways came from the observation that cytokines, such as the T helper-1 (T_H1)-cytokines interferon- γ (IFN- γ) and tumor necrosis factor (TNF) [14] or transforming growth factor- β (TGF- β) [13], can drive cancer cells into permanent growth arrest (Fig. 2c). This is astonishing as senescence was mainly considered to be an intrinsic antitumor mechanism. Cytokine-induced senescence (CIS) is the first example of an extrinsic senescence pathway leading to a permanent stop of the cell cycle. For the

proinflammatory T_H1 cytokines, the senescence signaling pathways have been partially deciphered: permanent growth arrest needs the simultaneous activation of TNF receptor 1, IFN- γ -signaling, and downstream stabilization of the prosenescent p16^{Ink4a}/Rb pathway [14, 15]. CIS also occurs in vivo after adoptive transfer of tumor-associated antigen (TAA)-specific T_H1 cells in transgenic rat-insulin promoter T antigen (RIP-Tag) mice (Fig. 2d) [14], or after vaccination of sarcoma-bearing mice with an IL-12 transcribing gene construct that induces IFN- γ - and TNF-mediated immune responses [15]. This demonstrates for the first time that (i) exogenous signals can override endogenous proliferative signals in cancer cells and (ii) that the immune system is able to restrict cancer growth by senescence induction without eradication of the cancer cells.

2 The immune system strikes back

2.1 Immune destruction and immune surveillance of cancer

Apart from the destruction of tumor cells by chemotherapy, radiation therapy or cytotoxic immune therapy, novel treatment options appear that control cancers without complete eradication. Some of these treatment options take advantage of the immune system: (i) adoptive transfer of tumor-specific, non-cytotoxic T helper cells may lead to durable clinical remission in melanoma patients [39] or to tumor dormancy in TAA-driven islet-cell cancer [40] and (ii) enhancement of T cell-mediated antitumor immune response in patients with stage IV melanoma or non-small-cell lung cancer. Here, blocking antibodies directed against immune checkpoints, e.g., primary monoclonal antibodies (mAbs) against the programmed death 1 (PD-1) receptor or its ligand PD-L1. The therapeutic efficiency may be enhanced by combining these mAbs with a mAb against cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4) [41–44]. The mechanisms underlying the observed immunotherapeutic effects are still to be defined in detail. These antibodies can destroy cancers at least in part [45]. However, under most conditions, tumors of patients are not completely eradicated and the responding patients continue to live with stable disease. Thus, at the beginning of immune checkpoint inhibitor therapies, the tumor load tends to decline, most probably due to infiltration of cytotoxic immune cells [42, 43, 46–49]. After this first cytotoxic phase, the remaining tumor or metastases tend to stay at a constant level but will not disappear [50, 51]. This indicates that immunotherapy may follow the *defensive wall* concept, which relies on non-toxic control of the tumor burden [52–54] and which is based on the induction of tumor dormancy. Tumor dormancy is considered as an equilibrium between cancer cell proliferation and killing of cancer cells [55, 56] with apoptosis or

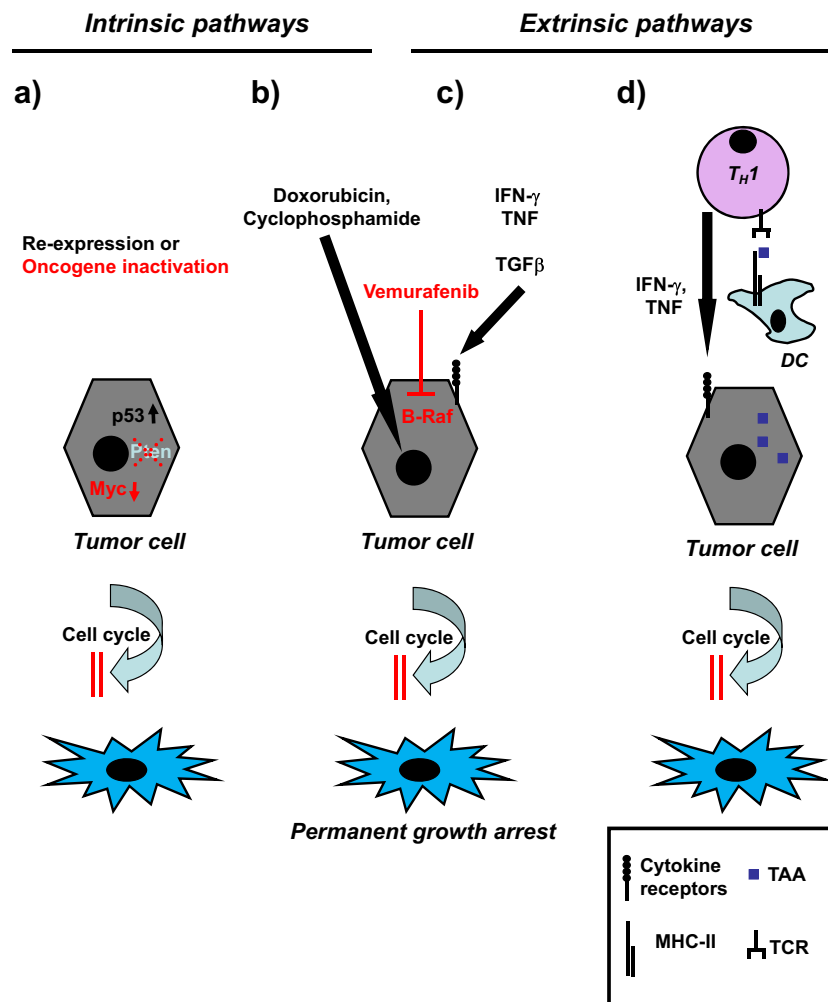

Fig. 2 Pathways of therapy-induced tumor cell senescence. Tumor cell senescence during therapy is induced either by intrinsic (a, b) or extrinsic pathways (c, d). **a** Molecular induction of cellular senescence can be realized by reexpression of pro-senescence factors (e.g., p53), complete loss of Pten, or oncogene inactivation (e.g., Myc). These molecular manipulations eventually lead to permanent growth arrest of tumor cells. **b** Different drugs, such as doxorubicin or cyclophosphamide, target the DNA of the cycling tumor cells leading to DNA stress which in turn induces a permanent cell cycle arrest. More specific drugs, e.g., the B-Raf kinase inhibitor vemurafenib, target intracellular signaling pathways and also lead to permanent cell cycle arrest. **c** Different cytokines, such as IFN- γ , TNF or TGF- β , bind to their specific receptors on the surface of the tumor cells. Activation of the cytokine

receptors then triggers intracellular signaling pathways leading to permanent cell cycle arrest. **d** Immune cells are also able to induce extrinsic senescence in tumor cells. Here, tumor-specific T_H1 cells are activated by MHC-II-positive DCs. After activation, the T_H1 cells secrete the soluble factors IFN- γ and TNF in the vicinity of the tumors. The secreted cytokines then bind to their specific receptors on the surface of the tumor cells thereby activating intracellular senescence pathways. *BRAF* proto-oncogene B-Raf or v-Raf murine sarcoma viral oncogene homolog B1, *DC* dendritic cells, *IFN- γ* interferon- γ , *MHC-II* major histocompatibility complex class II, *p53* cellular tumor antigen p53, *Pten* phosphatase and tensin homolog deleted on chromosome 10, *TAA* tumor-associated antigen, *TCR* T cell receptor, *TGF- β* transforming growth factor- β , *T_H1* T helper-1 cells, *TNF* tumor necrosis factor

immune cell-mediated lysis of cancer cells being the main killing mechanisms. This interpretation of the state of *silent tumors* has now been complemented by four non-toxic mechanisms, namely (i) active cell cycle control through regulation of cyclin-dependent kinases [57]; (ii) induction of cellular senescence [9, 14, 15, 58]; (iii) control of differentiation by regulating inhibitor of DNA binding (ID) proteins [59]; and (iv) inhibition of angiogenesis [60].

Evasion from immune-mediated control of tumors has been added to the six original hallmarks of cancer [61]. As shown in Fig. 3, control of tumors by the immune system can

be divided into a cytotoxic branch leading to tumor eradication and a non-cytotoxic branch leading either to stable disease or tumor regression. Immune destruction of tumors relies on cellular immunity: (i) cytotoxic T cells (CTLs) (Fig. 3a) or natural killer cells (NK) (Fig. 3b) specifically attack tumors by releasing pore-forming perforin together with proteases such as granzyme B or soluble toxic factors such as TNF [55, 56, 62–64]; (ii) specific CTLs may directly target the cancer cells by inducing death receptor-dependent apoptosis *via* the cluster of differentiation 95 ligand/cluster of differentiation 95 (CD95L/CD95) death-inducing signaling complex (for

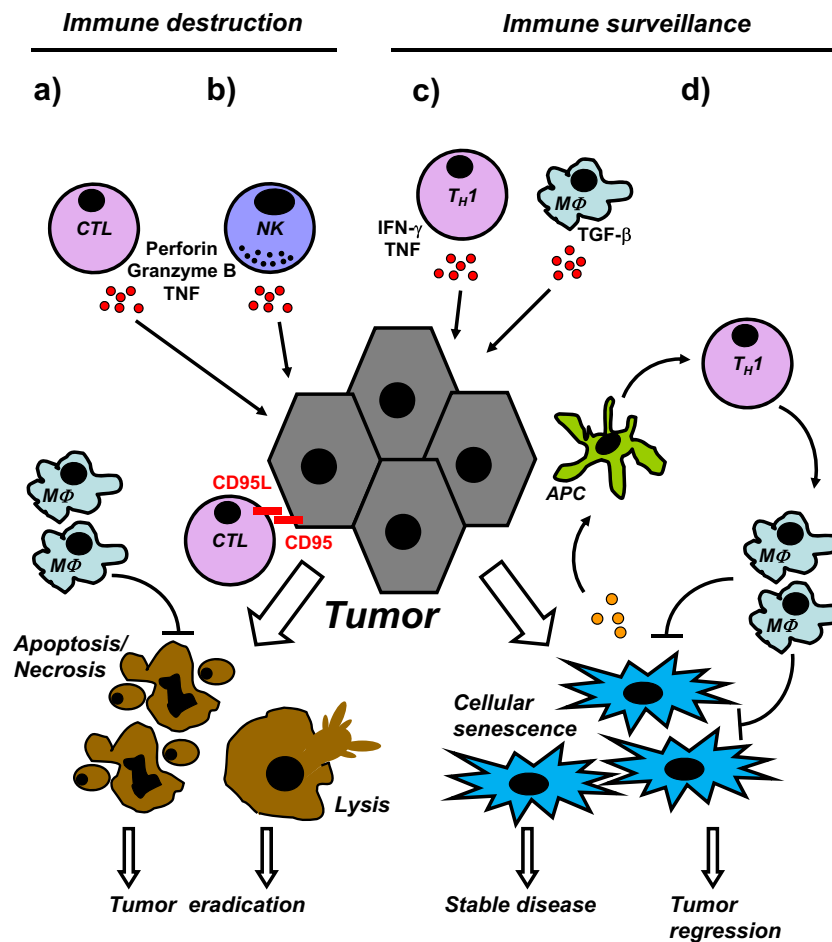

Fig. 3 Toxic and non-toxic pathways of immune system-mediated tumor suppression. The control of tumors by the immune system is achieved by immune destruction (a, b) or immune surveillance (c, d). **a** CTL either indirectly or directly attack tumor cells by secretion of toxic factors, such as perforin, granzyme B, or TNF, or by planting a kiss of death via CD95L-CD95 interaction and induction of the apoptosis cascade. This leads to tumor cell death by apoptosis, clearance of apoptotic bodies by macrophages, necrosis, or to tumor cell lysis. Finally, the immune system completely eradicates the tumor. **b** NK cells, like CTL, indirectly attack tumor cells by secretion of toxic substances, such as perforin, granzyme B, or TNF. This leads to tumor cell death and complete eradication of the tumor. **c** T_H1 cells or macrophages silence tumor cells by secretion of $IFN-\gamma$ and TNF or $TGF-\beta$, respectively. After binding to their specific

receptors on the surface of the tumor cells, the cytokines activate intracellular senescence pathways leading to permanent cell cycle arrest and stable disease. **d** Senescent tumor cells may also be cleared. Molecular factors released by senescent tumor cells lead to activation of APC. The APCs then stimulate a T_H1 cell response followed by activation of macrophages which in turn mediate the clearance of senescent cancer cells. If senescence induction and subsequent clearance of senescent tumor cells is effective, immune surveillance may also induce tumor regression. *APC* antigen-presenting cells, *CD95* cluster of differentiation 95, *CD95L* cluster of differentiation 95 ligand, *CTL* cytotoxic T cells, *IFN- γ* interferon- γ , *MΦ* macrophages cells, *NK* natural killer cells, *TGF- β* transforming growth factor- β , *T_{H1}* T helper-1, *TNF* tumor necrosis factor

review see [62]). If tumor immune destruction is successful, the apoptotic cells will be cleared by macrophages and the tumors will be eradicated. In addition, it has been shown that the immune system can also control tumors by senescence surveillance, a mechanism mainly based on cytokine-induced cellular senescence (Fig. 3c) and an immune-cell-mediated clearance pathway (Fig. 3d). Senescence has been shown to be induced *in vivo* in murine islet cell tumors by a combination of $IFN-\gamma$ and TNF released from tumor-specific T_H1 cells in the vicinity of the tumors [14]. Similarly, human sarcoma cell lines can be driven into senescence by IL-12-mediated induction of a T_H1 -phenotype in human T cells [15]. In this line, it has been demonstrated that the loss of

$IFN-\gamma$ pathway genes in cancer cells serves as a mechanism of resistance during immune checkpoint inhibitor therapies [65] and that the disruption of cyclin-dependent kinase 5 (Cdk5) strengthens antitumor immunity [66]. Likewise, $TGF-\beta$ originating from macrophages was shown to induce cellular senescence in lymphoma cells [13]. Thus, senescence induction alone leads to permanent growth arrest and stable disease with a remarkable prolongation of the survival of death-prone RIP-Tag mice [40]. In the long run, however, it may be necessary that senescent cancer cells become cleared: the SASP of N-ras-expressing senescent hepatocytes leads to activation of professional antigen-presenting cells (APCs) which in turn drive a T_H1 cell response followed by activation

of macrophages. One concept then suggests the subsequent clearance of senescent cancer cells by activated macrophages [16]. Yet, it remains unclear whether elimination of senescent cells always supports cancer cure or whether it may on the contrary promote cancer progression [67]. Senescence-inducing treatment of cancer patients is apparently based on re-enhancement or restoration of dormant intrinsic pathways. As survival with silenced tumors or with disseminated, silenced tumor cells is possible [41, 52], cancer patients will benefit from successful restoration of intrinsic senescence surveillance. In addition, it is likely that the resulting side effects of non-cytotoxic, pro-senescence therapies should be less severe as compared with cytotoxic regimens [68]. However, similar to cytotoxic tumor treatment, the benefits of pro-senescence therapy described above are only effective if the vast majority of the tumor cells is driven into senescence. Furthermore, the resting state of the silenced cancer cells has to be maintained, either by a permanent growth arrest or by exogenous (immune)-signals that keep the cancer cells silent. The main problems of senescence surveillance of tumors which have to be solved in the near future are therefore: (i) fast growing tumor cells, e.g., acute leukemias, may escape senescence surveillance [14, 15]; (ii) resting tumor cells may eventually awake and start regrowing if CIS turns out to be reversible, at least in some very aggressive cancers; (iii) the fate of non-proliferating tumor stem cells is unclear; (iv) the regeneration of normal tissues may be impaired; and (v) chronic inflammation [61] and some molecular components of the SASP [1, 17, 69] may even promote tumorigenesis in neighboring premalignant cells.

2.2 Evolutionary aspects of immune destruction and immune surveillance of cancer

Eradication of tumors is mainly based on cytotoxic principles, and the biological targets of different chemotherapeutics are genomic DNA (genetic code) as in the case of epirubicin [22], the plasma membrane (outward demarcation of the cell) as in the case of miltefosin [70], or the cytoskeleton as in the case of taxol [22]. This holds also true for the destruction of tumors by the immune system. It is generally accepted that apoptosis induction by death receptors (e. g., CD95/CD95L, TNF/TNFR1, etc.) finally leads to caspase-dependent DNA fragmentation [19, 22, 62] whereas the perforin/granzyme B system leads to target cell lysis, cell membrane rupture, and activation of specialized serine proteases [63, 64]. However, if DNA fragmentation is incomplete, mutated tumor cell clones might emerge and a Darwinian selection process is triggered [71]. This is to say that the vast majority of mutated tumor cells carrying large genomic aberrations (such as loss or gain of whole chromosome arms) will die, but those mutated cells that survive will restart proliferation and lose important endogenous or exogenous control mechanisms. Uncontrolled

proliferation then leads to accumulation of additional DNA damage and chromosomal chaos. Together, the genetic instability of cancers and the highly selective local microenvironmental forces, e.g., hypoxia, acidosis, and reactive oxygen species, are able to further promote somatic evolution. In addition, cytotoxic regimens impose strong selection pressures on the surviving cancer cells; the treatment should therefore rather enhance the evolutionary rate and promote selection of mutated cancer clones [71].

In clear contrast to conventional chemotherapy, immune surveillance of tumors is not exclusively dependent on tumor cell destruction, and the biological target structures are mainly signal transduction pathways and the respective signaling molecules, e.g., receptors, adaptor proteins, kinases, or kinase inhibitors. For example, CIS by T_H1 cell cytokines (IFN- γ , TNF *etc.*) leads to stabilization of the p16^{Ink4a}/Rb pathway thereby permanently arresting the tumor cells in the G0/G1 phase of the cell cycle [14]. Furthermore, tumor-specific T_H1 cells that can now be generated for the use in humans [72] induce the production of antiangiogenic chemokines, e.g., chemokine (C-X-C motif) ligand 9 (CXCL9) and chemokine (C-X-C motif) ligand 10 (CXCL10) [14, 40] thereby leading to isolation of the tumor cells [40, 54]. Inhibitory antibodies, on the other hand, target *cellular exhaustion pathways* by interfering with ligand-receptor interactions thereby maintaining the antitumoral activity of specific immune cells [41]. Last but not least, small molecules targeting signal transduction pathways, such as proto-oncogene B-Raf (BRAF) inhibitors or oncogenic BCR-ABL gene fusion product (BCR-ABL) inhibitors, specifically inhibit kinases thereby driving the cancer cells into cell cycle arrest [38]. The common feature of those strategies is that they directly or indirectly impair cancer cell proliferation. The selection pressure on the arrested cancer cells is therefore strongly reduced and the treatment should not promote somatic evolution.

2.3 Metabolic aspects of immune destruction and immune surveillance of cancer cells

Cancer cells are distinct from normal cells as they switch from aerobic to anaerobic metabolism, even in the presence of sufficient oxygen support. Thus, they use anaerobic glycolysis for adenosin triphosphate (ATP) production rather than oxidative phosphorylation, the so called *Warburg effect* [1, 61]. As a result, the oxygen consumption by the mitochondria is reduced. The cells produce lactic acid which is released into the blood and transported to the liver where it is used for gluconeogenesis.

Chemotherapy- or radiation therapy-induced apoptosis should enhance the switch of tumors towards anaerobic metabolism. In this line, it has been shown that drug-induced apoptosis signaling leads to dissipation of the mitochondrial membrane potential, release of cytochrome c, and

downstream activation of caspase-3 [22, 73]. Thus, oxidative phosphorylation *via* the mitochondrial respiratory chain is further inhibited during drug-induced apoptosis.

On the other hand, cancer cells undergoing oncogene-induced senescence (OIS) switch back to mitochondrial oxidative phosphorylation. By regulating the mitochondrial gate keeper pyruvate dehydrogenase, senescent cells make enhanced use of pyruvate in the tricarboxylic acid cycle [74]. This causes increased respiration and oxidative stress thereby counteracting metabolic reprogramming in the cancer cells. Interestingly, premature senescence is often accompanied by activation of the target of rapamycin (TOR) pathway which is considered to be a central regulator of mammalian metabolism and physiology. Activation of TOR in the context of cell cycle arrest then leads to *real* senescence with irreversible loss of the regenerative potential [75]. Metabolic reprogramming as seen by the Warburg effect provides tumor cells with ATP and with the substrates required for biomass generation. Recently, it was demonstrated that the mitochondrial nicotinamide adenine dinucleotide (NAD)-dependent deacetylase SIRT3 is a crucial regulator of the Warburg effect by destabilizing hypoxia-inducible factor-1 α (HIF-1 α). HIF-1 α downregulation then leads to repression of glycolysis and inhibition of proliferation of breast cancer cells thereby pointing to a new tumor suppressor mechanism [76]. Activation of the immune system is also connected with cellular metabolism. It has been shown that succinate, an important metabolite of the tricarboxylic acid cycle, serves as an inflammatory signal that induces interleukin-1 β (IL-1 β) through HIF-1 α [77]. Thus, there are several experimental hints that tight connections between the regulation pathways of the cell cycle and the main metabolic pathways of eukaryotic cells, i.e., glycolysis, tricarboxylic acid cycle, and oxidative phosphorylation, really exist. Future work will decipher the signaling networks underlying inflammation, oncogenesis, cancer cell senescence, and metabolic reprogramming.

3 Outlook: combining cytotoxic and pro-senescence therapy

Due to the still unsatisfactory clinical success of cancer treatments, additional efforts including new concepts are urgently needed. As therapy resistance is the most important drawback of the main cytotoxic cancer regimens, it is reasonable to target different cellular structures or hallmarks of cancer. Nevertheless, a combination approach may even be successful if similar cellular signaling pathways are inhibited or induced at the same time. For example, the combination of T cell-activating anti-PD-1 and anti-CTLA-4 antibodies showed improved clinical activity that clearly exceeded monotherapy [41]. The finding that it is possible to induce extrinsic premature senescence by treatment of cancer cells with a cytokine

combination of IFN- γ and TNF [14] opens the way to non-toxic treatment options. Both cytokines are endogenous signaling molecules which are already available as drugs. Their toxicity profiles are known and less toxic alternatives, such as IFN- α , are at hand. More importantly, stopping the fulminant growth of malignant cancers by CIS will thus perfectly complement the cytotoxic effect of most anti-cancer drugs. The combination of cytotoxic drugs in the acute phase of the disease with CIS as therapy during the consolidation phase is one of the most promising approaches which may be introduced into clinical practice in the near future. In conclusion, besides the development and introduction of new drugs for cancer cell destruction or senescence induction, clinical research should also focus on optimized strategies that combine already approved medication with CIS.
